REGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE

FELLOW OF GONVILLE AND CAIUS COLLEGE, ETC. ETC.

PREFACE TO THIRD EDITION

THE continued expression of appreciation with which this work has been received has been a source of great satisfaction and encouragement to the authors and the editor.

The third edition has been thoroughly revised and brought up-to-date.

The only alterations in the classification and general arrangement are that the articles on Yellow Fever, Phlebotomus Fever and Dengue have been moved from the section on Spirochætal Infections to that on Infectious Diseases of Doubtful or Unknown Ætiology, the article on Verruga Peruviana from the section on Tropical Diseases of Doubtful or Unknown Nature to that on Tropical Diseases of Doubtful or Unknown Ætiology, that on Rickets from Diseases of Metabolism to Deficiency Diseases, the article on Arterial Blood-pressure has been transferred from the early part of Diseases of the Circulatory System to the end of this section, that on Uræmia has been placed after Nephritis, the article on Toxæmic Kidney has been included in that on Nephritis, and several other modifications in the classification of the latter disease have been made.

New articles have been added on the following : Melioidosis, Lead Tetra Ethyl Poisoning, Carbon Monoxide Poisoning, Basal Metabolism, Lipodystrophia Progressiva, Vitamins, Tumours of the Thymus, Polyglandular Syndrome, Internal Secretion of the Sex Glands, Achalasia of the Pharyngo-(Esophageal Sphincter (Plummer-Vinson Syndrome), Intestinal Carbohydrate Dyspepsia, Megacolon in Adults, Familial Icterus Gravis Neonatorum, Biliary Colic without Gallstones, Sickie-celled Anæmia, Congenital Auriculo-Ventricular Block, Intraventricular (Arborisation) Block, Nodal Rhythm, Ventricular Fibrillation, Infarction of the Heart, Syphilitic Affections of the Aorta, the Heart, and the Pericardium, Thrombo-Angiitis Obliterans, Periarteritis Nodosa, Congenital Laryngeal Stridor, Diseases of the Diaphragm, Hyperpietic Kidney, Senile or Atheromatous Kidney, Acrocyanosis, Oidiomycosis, Schilder's Disease (Encephalitis Periaxialis), Morvan's Disease, The Veronal Habit, Stupor, and Chronic Hallucinatory Psychosis.

Other new matter has reference to : Oculogyric Crises in Encephalitis, The Prophylaxis of Syphilis by the Administration of Arsenical Preparations, The Use of Malaria and other Pyrogenic Agents in the Treatment of Syphilis, The Treatment of Malaria by "Plasmochin" or "Plasmoquin," The Serum Prophylaxis of Measles, The Dick Test, The Method of Inducing Immunity in Scarlet Fever, The Use of Anti-Scarlatinal Serum, Laboratory Tests for

Smallpox, The Treatment of Blackwater Fever and Sprue by Blood Transfusion, Diagnostic Tests of Drunkenness, The Pathology of Achalasia of the Cardia and of the Anal Sphincter (Hirschsprung's Disease), Cholecystography, Atypical Chloromata, The Clinical Manifestations of the Various Degrees of Cardiac Failure, Adrenalin Therapy, Barium Therapy, The Surgical Treatment of Mitral Stenosis, Paradoxical Embolism, Electrical Treatment of Raynaud's Disease, Protein Cutaneous Tests in Asthma, Lipiodol Investigations and The Surgical Treatment of Bronchiectasis, The Technique of Artificial Pneumothorax Treatment, Nephrosis, The Treatment of Scalp Ringworm by Thallium Acetate, Nuclear Ophthalmoplegia, The Signs of Local Lesions of the Brain, Spontaneous Subarachnoid Hæmorrhage, Amaurotic Family Idiocy, and Dementia Præcox.

The following articles have been wholly or largely rewritten : Glandular Fever, The Treatment of Acidæmia, Alkalæmia, and Allied Conditions, The Treatment of Diabetes Mellitus, The Treatment of Obesity, Diseases of the Suprarenal Glands, The Treatment of Hyperthyroidism, Diseases of the Parathyroid Glands, Diseases of the Pineal Gland, Chronic Gastritis, The Treatment of Pernicious Anæmia, Purpura, Gaucher's Type of Splenomegaly, Functional Disorders of the Heart, Adams-Stokes Syndrome, Arterial Hypertrophy, The Treatment of Malignant Disease of the Larynx, The Estimation of Renal Function, Hepato-Lenticular Degeneration (Progressive Lenticular Degeneration), Disseminate Sclerosis, and Epilepsy.

Four illustrations (Figs. 11, 89, 90, and 91) have been added.

It is a great pleasure to offer to each of the contributors my warmest thanks.

It is my confident opinion that the book will continue to be considered a credit to the London School of Medicine.

FREDERICK W. PRICE.

133 HARLEY STREET, LONDON, W.

September 1929.

PREFACE TO SECOND EDITION

THE very favourable reception of the first edition has been most gratifying and encouraging to the authors and editor. The second edition has been thoroughly revised and brought up-to-date. The only alterations in the classification and general arrangement are that the article on Rickets has been moved from the section on Deficiency Diseases to that on Diseases of Metabolism, and the article on Mikulicz's Syndrome from the section on Diseases of the Salivary Glands to that on Diseases of the Lymphatic System. Articles on Tularæmia, Botulism, Apical Dental Infection, Chylous Diarrhœa, Chronic Duodenal Ileus, and Tuberculosis of the Kidney have been added. Other new matter includes articles on the Schick Test in Diphtheria and the Method of Producing Active Immunity, the Dick Test in Scarlet Fever, the Investigation of Diseases of the Liver and Pancreas, Quinidine Therapy, the Pathology of Auricular Fibrillation and Auricular Flutter, Mental Sequelæ of Encephalitis Lethargica, and Paraphrenia. The following articles have been wholly or largely re-written : the Pathology of Scarlet Fever, Diabetes Mellitus, Secretory Disorders of the Stomach, Diverticulosis, Hirschsprung's Disease, Cholecystitis, Aphasia and other Defects of Speech, Epilepsy, Hysteria, Neurasthenia, and Dystrophia Myotonica. Fourteen illustrations (Nos. 9, 10, and 12-23) have been added.

Again I wish to offer to each of the contributors my warmest thanks.

FREDERICK W. PRICE.

133 HARLEY STREET, LONDON, W.

January 1926.

PREFACE TO FIRST EDITION

It is generally recognised that within recent years there has been a great advance in knowledge throughout the domain of Medicine. As an example of this might be cited the branch of cardiology. As the result of the introduction of the clinical polygraph and of the electrocardiograph we are now able to analyse the cardiac action in a manner which was never possible before, and many of the problems in the study of diseases of the heart which have baffled clinicians for generations have been practically solved, while others are in process of solution. In the department of neurology the progress made has been scarcely less notable. It seemed to me, therefore, that now, more than ever, it has to be acknowledged that it is beyond the scope of any authority, however varied his range of knowledge, to do full justice to the ever-widening field of Medicine, and that a useful purpose might be served by the publication of a work of moderate compass and in one volume, in which the different branches of Medicine were dealt with by authors who have made a special study of each. It has also been thought advisable to include sections on Diseases of the Skin and Psychological Medicine. Tropical Diseases are also included.

In order to secure greater uniformity of method and style, I have generally adopted the principle of allotting a whole section to one author, or to two writing in collaboration, instead of enlisting the services of a large number of writers. I confidently anticipate that it will be recognised that I have been most fortunate in the selection of the various contributors to the volume, and I wish to offer to each of them my warmest thanks. I also desire to express my gratitude to Dr. A. P. Beddard, for the time he has very generously placed at my disposal, and for much valuable advice. It is a pleasant duty gratefully to acknowledge my indebtedness to Dr. Claude B. Ker for the use of blocks of figures taken from his *Manual of Fevers*, and to Dr. James Collier and Sir James Purves Stewart for a block of figure 96.

It is my earnest hope that the book may be considered a credit to the London School of Medicine.

FREDERICK W. PRICE.

133 HARLEY STREET, LONDON, W.

January 1922.

CONTRIBUTORS

- W. J. ADIE, M.B., F.R.C.P., Physician to Charing Cross Hospital; Physician to Out-Patients, National Hospital for Nervous Diseases, Queen Square; Physician to the Royal London Ophthalmic (Moorfields) Hospital.
- HAROLD S. BARWELL, M.B., F.R.C.S., Consulting Surgeon for Diseases of the Throat and Ear, St. George's Hospital.
- G. E. BEAUMONT, M.A., M.D., F.R.C.P., Physician, with charge of Out-Patients, Middlesex Hospital; Physician to the Brompton Hospital for Consumption and Diseases of the Chest.
- CHARLES R. BOX, M.D., B.Sc., F.R.C.P., F.R.C.S., Consulting Physician to St. Thomas's Hospital; Senior Physician to the London Fever Hospital.
- W. LANGDON BROWN, M.A., M.D., F.R.C.P., Physician to St. Bartholomew's Hospital.
- LIEUT.-COLONEL W. BYAM, Lecturer on Tropical Medicine, St. George's Hospital Medical School.
- JAMES COLLIER, M.D., B.Sc., F.R.C.P., Consulting Physician and Emeritus Lecturer in Neurology, St. George's Hospital; Physician to the National Hospital for Nervous Diseases, Queen Square.
- GEOFFREY EVANS, M.D., F.R.C.P., Physician with charge of Out-Patients, St. Bartholomew's Hospital.
- GEORGE GRAHAM, M.D., F.R.C.P., Assistant Physician, St. Bartholomew's Hospital.
- A. M. H. GRAY, C.B.E., M.D., F.R.C.P., F.R.C.S., Physician in charge of the Skin Department, University College Hospital; Physician for Skin Diseases, Hospital for Sick Children, Great Ormond Street.
- BREVET-COLONEL L. W. HARRISON, D.S.O., M.B., Ch.B., M.R.C.P., Director of the Venereal Department, St. Thomas's Hospital.
- SIR THOMAS HORDER, Bart., M.D., B.Sc., F.R.C.P., Physician to St. Bartholomew's Hospital.
- ARTHUR F. HURST, M.A., M.D., F.R.C.P., Senior Physician to Guy's Hospital.
- ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital; Physician to the Hospital for Sick Children, Great Ormond Street.

- O. LEYTON, M.A., M.D., D.Sc., F.R.C.P.,** Physician to the London Hospital.
- G. CARMICHAEL LOW, M.A., M.D., F.R.C.P.,** Senior Physician to the Hospital for Tropical Diseases, Endsleigh Gardens; Senior Physician to the Seamen's Hospital, Royal Albert Docks, E.; Consulting Physician in Tropical Disease, Tilbury Hospital.
- ERIC DANVERS MACNAMARA, M.A., M.D., F.R.C.P.,** Physician for Mental Disorders to Charing Cross Hospital; Physician to the West End Hospital for Nervous Diseases.
- JOHN MATTHEWS, M.B.,** Assistant in the Inoculation Department, St. Mary's Hospital.
- M. S. PEMBREY, M.A., M.D., F.R.S.,** Lecturer in Physiology, Guy's Hospital; Professor of Physiology, University of London.
- R. H. A. PLIMMER, D.Sc.,** Professor of Chemistry in the University of London at St. Thomas's Hospital Medical School.
- FREDERICK W. PRICE, M.D., F.R.S.(Edin.),** Physician to the National Hospital for Diseases of the Heart; Consulting Physician to the Royal Northern Hospital.
- E. G. SLESINGER, O.B.E., B.Sc., M.S., F.R.C.S.,** Assistant Surgeon to Guy's Hospital.
- THEODORE THOMPSON, M.A., M.D., F.R.C.S., F.R.C.P.,** Physician to the London Hospital.
- HUGH THURSFIELD, M.D., F.R.C.P.,** Consulting Physician to St. Bartholomew's Hospital; Physician to the Hospital for Sick Children, Great Ormond Street.
- SIR W. H. WILLCOX, K.C.I.E., C.B., C.M.G., M.D., B.Sc., F.R.C.P.,** Physician to St. Mary's Hospital.
- R. A. YOUNG, C.B.E., M.D., B.Sc., F.R.C.P.,** Senior Physician to the Middlesex Hospital; Physician to the Brompton Hospital for Consumption and Diseases of the Chest.

DISEASES OF THE SKIN

	PAGE
INTRODUCTORY	1270
I. GENERAL DESCRIPTION OF SKIN DISEASES	1273
II. CONDITIONS PREDISPOSING TO SKIN DISEASES	1274
1. Disorders of Secretion	1274
(a) Anidrosis	1274
(b) Xerodermia and Ichthyosis	1274
(c) Hyperidrosis	1275
(d) Seborrhœa	1276
2. Disorders of Sensation	1277
Pruritus	1277
3. Disorders of Circulation	1280
(a) Acrocyanosis	1280
(b) Chronic Vascular Stasis of the Lower Limbs	1280
(c) Rosacea—Acne Rosacea	1280
III. INFLAMMATIONS OF THE SKIN	1282
(A) The Superficial Inflammatory Dermatoses	1282
1. Dermatitis from Chemical Irritants	1284
2. Dermatitis from Heat and Cold	1285
3. Dermatitis from Actinic Rays	1286
4. Eczema	1287
5. Dermatitis from Mechanical Irritants	1293
(a) Scratch Eruption	1293
(b) Callosities and Corns	1293
6. Dermatitis <i>Artefacta</i>	1294
7. Dermatitis from Bacterial Irritants	1295
(a) Streptococcal Infections	1295
Impetigo Contagiosa	1295
Pemphigus Neonatorum	1296
Ecthyma	1297
Superficial Streptococcal Dermatitis	1297
(b) Staphylococcal Infections	1298
Bockhart's Impetigo	1298
Furuncle	1299
Carbuncle	1300
Sycosis Barbæ	1300
(c) Anthrax Infectious (see p. 107).	
(d) Diphtheria Infections	1301
(e) Infections by the Seborrhœic Organisms	1302
Seborrhœic Dermatitis	1302
Acne Vulgaris	1304
Acne Varioliformis	1306
Acne Keloid	1307
8. Dermatitis due to Fungi	1307
(a) Ringworm	1307
Ringworm of the Scalp	1308
Ringworm of the Beard	1310
Ringworm of the Glabrous Skin	1311
Ringworm of the Nails	1313

	PAGE
(b) Oidiomycosis	1313
(c) Favus	1314
(d) Tinea Versicolor	1314
(e) Erythrasma	1315
(f) Lepothrix	1315
9. Dermatitis due to Animal Parasites	1315
(a) Bites and Stings	1315
(b) Pediculosis	1316
(c) Scabies	1318
(B) The Deep Inflammatory Dermatoses	1320
1. Toxic Eruptions	1320
(a) Drug Eruptions	1321
(b) The Erythemata	1323
(c) Granuloma Annulare	1325
(d) The Purpuras	1325
(e) The Urticarias	1325
(f) Prurigo	1328
(g) Dermatitis Herpetiformis	1329
(h) Pemphigus	1330
(i) Dermatitis Exfoliativa	1332
2. Eruptions due to Bacteria and Fungi	1334
(a) Tuberculosis Cutis	1334
Lupus Vulgaris	1334
Lupus Verrucosus	1336
Local Tuberculous Ulcers	1336
Scrofuloderma	1336
(b) The Tuberculides	1337
The Lichenoid Tuberculide	1337
The Acneiform Tuberculide	1337
The Papulo-necrotic Tuberculide	1337
The Gummatous Tuberculide (Bazin's Disease)	1338
(c) Lupus Pernio	1338
(d) The Sarcoids	1339
(e) Gonorrhœal Keratosis	1340
(f) Sporotrichosis	1340
3. Xanthoma	1340
(C) Inflammatory Dermatoses of Nervous Origin	1341
(a) Herpes Zoster	1341
(b) Herpes Febrilis	1342
(c) Herpes Preputialis	1343
(D) Inflammatory Dermatoses of Unknown Origin	1343
1. Psoriasis	1343
Parapsoriasis	1345
Pityriasis Rubra Pilaris	1346
4. Pityriasis Rosea	1346
5. Lichen Planus	1347
6. Lupus Erythematosus	1349
7. Scleroderma	1350
8. Sclerema Neonatorum	1351
(E) The Lympho-granulomata	1352
1. Leukæmia and Lymphadenoma Cutis	1352
2. Mycosis Fungoides	1352

A TEXTBOOK OF THE PRACTICE OF MEDICINE

SECTION I

FEVER

FEVER is a complex response, or reaction, to infection, and, as such, is to be regarded as a protective mechanism, or one of the defences of the body, closely connected with the development of immunity. Fever is not the disease; the invading enemy is the infective organism and fever is evidence of the fight maintained by the invaded body.

The process of fever in the infective diseases is associated so closely with a rise in the temperature of the patient that the term "fever" has been often, and is still, used to denote the heightened temperature. A similar ambiguity has arisen in the use of the medical term, "pyrexia." Some writers have used it to signify a heightened bodily temperature; others have reserved it for the rise of temperature associated with infection, and others have used it sometimes in the one sense, sometimes in the other. In this article the use of the term "pyrexia" will be restricted to the rise of temperature, which is so often a marked characteristic of fever, and the high temperature produced by causes other than infection will be described as "hyperthermia." Fever is a complex process in which a disturbance in the temperature is only a part of the reaction of the organism.

The significance of fever will be recognised more readily by a study of the regulation of temperature and metabolism and the means whereby this regulation may be disturbed. The knowledge so obtained can be used as a basis for treatment. Stress will be laid upon temperature, for the practical reason that the physician, by the intelligent use of the thermometer, can study the disturbance of disease without resort to the complicated methods which are involved in the determination of the exchange of material in the body.

The regulation of temperature in health and during fever.—In the long process of evolution, in the constant struggle against heat and cold, the warm-blooded animal has developed its power of regulating its temperature so perfectly that its internal temperature is the same in the height of summer as in the depth of winter. In disease other conditions are present and may influence the temperature of the body in various ways.

A temperature raised above the normal level must be due in all cases to a disturbance of the balance between the production and the loss of heat;

this in turn must be caused by intrinsic or extrinsic factors or a combination of these. The simplest examples are muscular work and exposure to a hot and humid atmosphere; in the former the internal temperature may rise to 101° or 102° F. ($38^{\circ}\cdot33$ to $38^{\circ}\cdot89$ C.), owing to the great increase in the production of heat in the active muscles; in the latter case the loss of heat from the body may be prevented by the conditions of the surroundings. The usual rise of temperature produced by muscular work is beneficial, for it not only increases the activity of the respiratory centre, but also enables the oxygen-carrier, the hæmoglobin of the blood, to part more readily with its oxygen to meet the needs of the active tissues. On the other hand, the high temperature of the body produced by simple exposure to excessive heat and moisture increases the production of heat in the body directly the optimum temperature has been passed, and thus leads in a vicious circle to hyperthermia and death from heat-stroke. In the pyrexia of an infectious disease it has long been a question whether the rise of temperature is beneficial or detrimental to the patient or whether both possibilities may not exist, according to the amount and duration of the increased heat. It is necessary to consider the less complex cases in which the temperature is raised above the normal, for the processes involved throw light upon the nature of pyrexia; there is no reason to believe that some entirely new principle is involved.

Considered from such a point of view, pyrexia may be due to increased production or diminished loss of heat, or any combination of these which leaves a balance in favour of the production.

Production of heat.—The muscles and the glands are the chief seats of the production of heat, for although all the other tissues produce heat during oxidation their bulk is relatively small and their chemical changes comparatively slight. The muscles form 40 to 50 per cent. of the weight of the body; the liver and kidneys have a weight of 1579 and 250 grammes respectively.

The relation between muscular activity and the production of heat is notorious; even the child knows that it can warm its body on a cold day by running. Exact observations by the combined respiration apparatus and calorimeter have proved that the respiratory exchange and the production of heat bear a definite relation to work; the law of the conservation of energy applies to physiological processes. Gross muscular activity may double or treble the production of heat, and of this there is now no doubt. The difficulty, however, is that such activity is not seen in the process of fever and cannot be advanced without further consideration as the cause of pyrexia. During apparent rest, even during deep sleep, the muscles are active in a subdued form, which is called "tone." A further reduction in activity is produced by the paralysing effects of anæsthetics; the limbs are now limp; the respiratory exchange and the production of heat are reduced, it may be, to one-half the healthy minimum of sleep. Some investigators hold the view that the muscles have, apart from contraction, a special power of producing heat, an exaggeration of the process of oxidation which is common to all cells. The evidence upon which this is based appears to be insufficient. The relationship between the ordinary activity of muscle and the production of heat is shown clearly by comparative physiology; during the natural process of hibernation the warm-blooded mammal passes into a condition of torpor, its temperature may fall as low as 2° above the freezing-point, it responds to changes of external temperature in a similar

manner to that seen in cold-blooded animals. When the torpid animal awakes, the rise in the temperature of its body is accompanied by shivering; and in the marmot, in which the fore part of the body is warmed more rapidly than the hind parts, shivering may be seen in the region of the head and neck at a time when the hind limbs are still paralytic. In a rabbit, paralytic from section of the spinal cord directly below the shoulder girdle, the temperature of the mouth is higher than that of the rectum, especially when the unparalysed muscles are thrown into activity by the action of a stimulating drug. In pyrexia there is similar evidence; a rigor is involuntary muscular activity, shivering; the respiratory exchange and the production of heat are increased and may be, as experiments show, nearly doubled during the shivering produced by exposure to cold. If the temperature be raised above the optimum then the muscles would share in the general increased production of heat which is common to all the tissues, and during a long-continued fever would waste considerably. On these grounds a continuation of the contractions observed during rigor in the first stage of the fever, would not be necessary for the maintenance of the heat during the fastigium or second stage.

Loss of heat.—In the next place, the loss of heat demands consideration. Constriction of the cutaneous blood vessels diminishes the loss of heat, and the internal temperature will rise, if the production of heat in the body remains the same or is increased. During a rigor the patient complains of feeling cold; his teeth chatter and he shivers with cold, although his internal temperature is rising above the normal. As a sensitive being he is cold, for his sensations of temperature arise in his skin, not in his viscera; his skin is pale and cold from the spasm of the involuntary muscles of his vessels, and determinations of the surface temperature prove that it is below the normal. The onset of pyrexia is indicated by a rigor; the production of heat is increased, the loss of heat is diminished, the balance is disturbed, the heat of the body must rise.

Evidence, both clinical and experimental, indicates that at the onset of pyrexia the production of heat in the muscles is increased and the loss of heat from the skin is diminished. This comparison is with the condition of a fasting man at rest. The glandular source of heat would appear to be of relatively small importance, owing to the diminished appetite and intake of food, although it is true that the muscles would need for their activity the products of the glands of internal secretion, including the liver. When the pyrexia is continued other factors come into play; the increased production of heat due to the rigor of the onset may be replaced by that due to the rise of the temperature above the optimum; the diminished loss of heat due to the constriction of the cutaneous blood vessels will cease with the relaxation or dilatation of the vessels, but nevertheless, owing to the absence of sweating, the balance may be against the loss. The inefficiency of vascular dilatation and the importance of sweating are shown by the case of a man born without sweat glands but otherwise healthy; he was unable to do muscular work in summer owing to the abnormal rise in his temperature, and could compensate only when he worked in a shirt previously soaked in water. During the pyrexia of pneumonia the skin is abnormally hot, the vessels are dilated but the skin is dry; on the other hand, a great increase in the loss of heat occurs at the crisis, which is accompanied by profuse sweating.

Regulation of the production and loss of heat.—As far as the production and loss of heat are concerned, the process of pyrexia can be explained in accordance with ordinary physiological principles. The difficulty is to solve the question, What is the power which maintains the balance in health, and how is that balance disturbed in pyrexia? Some advance may be made by considering the means whereby the balance is maintained, suspended or abolished. The regulation of temperature depends upon the control of the nervous system over the production of heat in the muscles and glands and over the loss of heat by the skin and the respiratory tract; the control is exerted in response to sensations of heat and cold. There are some natural conditions which afford evidence upon these points.

The evolution of the capacity to regulate the temperature.—This can be traced in the animal series and in the individual animal. There are rudiments of this power in the so-called cold-blooded animals; in the lowest mammals, the monotremes, the capacity is imperfect; in the hibernating mammals it is suspended during torpidity, for they have retained some of the characteristics of their cold-blooded ancestors. Furthermore, young mammals born in a condition of immaturity need the warmth of their parent's body, for they themselves cannot maintain their temperature. The same is true of many newly hatched birds. On the other hand, there are examples, such as the guinea-pig, in which the nervous control is wonderfully developed even at birth; it is able to run about and maintain its temperature. This passage from the cold-blooded to the warm-blooded stage can be traced in the embryo chick during incubation. In all of these cases the power of regulating temperature appears to be bound up inseparably with the control of the voluntary muscles and the muscles of the blood vessels. Observations upon premature infants and the effects of baths upon weak and strong infants agree with the results of comparative physiology; a premature infant should be washed with oil, not with water, so that its loss of heat may be diminished, and an incubator is used to supply a warm environment, for an immature infant resembles in many respects a cold-blooded animal.

Influence of lesions of the central nervous system.—Experimental evidence has a similar significance. Anæsthetics will abolish for the time the power of regulation of temperature; so also will drugs, such as curare, and alcohol in large doses. The investigation is carried a stage further by observations upon the effects of lesions of the central nervous system. The cerebrum influences the regulation, but is not essential for the maintenance of the bodily heat. Pigeons can regulate their temperature after the complete removal of their cerebral hemispheres, and a similar operation upon a dog only curtails its range of adaptation to the temperature of its surroundings; in both cases the brainless animal is not paralysed, for it can perform complicated muscular movements and respond to cutaneous impulses. Similar evidence for man is incomplete, for the condition of anencephalic monsters does not appear to have been investigated sufficiently. Section of the spinal cord by cutting off the incoming and outgoing impulses produces a complex condition in animals and man; the control is lost in the paraplegic portions of the body, and, if the paraplegia is extensive, the condition may resemble that of a cold-blooded animal, the internal temperature varying with and in the same direction as the temperature of the surroundings. A man in whom paraplegia has been produced by a traumatic transverse section of the spinal

cord shivers with the muscles supplied by nerves above the lesion when he feels cold ; on the other hand, when he is hot he sweats only as far as the line between the non-paralysed and the paralysed portions of his skin. These conditions are in practice valuable indications of the position and severity of a spinal lesion. The method of exclusion leaves the control of the temperature in the mid-brain and medulla. For such a localisation confirmation can be obtained from the results of lesions of the basal ganglia produced by experiment or disease ; a disturbance of the temperature is so constant a feature of these lesions that the ganglia have been designated the "heat centres." It is possible, however, that the true interpretation is to be found in the evolution of the regulation of temperature, the connection of these ganglia with the incoming impulses from the skin and the outgoing impulses to the muscles. The response of these centres to heat and cold is usually due to sensations arising in the skin, but in some cases there is evidence that it may occur from direct action, through the medium of the blood, upon the excitability of the centres. Be this as it may, no explanation of the response can be offered as long as the nature of sensation is unknown. Notwithstanding this fundamental gap in knowledge, it is possible to make a further advance towards an explanation of pyrexia.

Influence of drugs.—The nervous control of the regulation of temperature can be influenced by drugs ; it can be paralysed by anæsthetics, and in its balanced effect can be disturbed in one direction or the other, so that the temperature rises with pyretics and falls with antipyretics. This comparison of pyrexia with the hyperthermia produced by drugs has yielded results of importance. There are no gross anatomical changes to be found in the nervous system as a characteristic of pyrexia, and the microscopic appearances, such as chromatolysis and other alterations in the neurons, are probably the effect, not the cause of pyrexia, for they can be seen in cases of heat-stroke produced experimentally in animals, or by accident in man.

The most interesting of the so-called pyretic drugs is tetrahydro- β -naphthylamine, which may raise the temperature as high as 112°I F. ($44^{\circ}\cdot 5\text{ C.}$). Its action is upon the central nervous system ; there is increased excitability, accompanied by muscular activity, spasms or convulsions, and at an early stage there is vaso-constriction in the cutaneous vessels. The production of heat, as measured by the respiratory exchange, is increased to a degree sufficient to explain the rise of temperature. It is of interest also that in some cases a lethal dose may cause the temperature to fall 3° or 4° below the normal.

Influence of micro-organisms.—In the pyrexia of fever the toxic agent must be sought in the micro-organism which has induced the disease. To produce pyrexia the animal is infected by an injection of a culture of the micro-organism, or it may be subjected to the filtered products obtained from the culture. Pyrexia is one of the reactions of the animal to the invasion of a pathogenic organism, and it may be a means of defence, evolved in the struggle for existence. Upon this more must be said at a later stage, for it is necessary now to consider in more detail the question whether the micro-organism attacks by producing a specific toxin, which will act upon the nervous system and disturb the regulation of temperature. It is well known that such toxins can be obtained by the action of bacteria ; it is sufficient to mention tuberculin as an example. The mode of action, however,

may be more complex, for, in addition to the specific toxin, the activity of the micro-organism may cause other changes in the chemical composition of the infected animal; some forms of protein and even excess of salts may be factors in the production of pyrexia.

A pyretic injected into the body causes a rise of temperature, hyperthermia, but it has been maintained throughout this article that pyrexia is more complex. It has indeed been long recognised that there are different types of pyrexia; there may be continuous "fever," remittent or intermittent, and the variation in the temperature may be peculiar to the disease and thus supply a diagnostic sign of great value. Increased production of heat and diminished loss of heat of the degrees to be found in fevers will not explain the pyrexia, for a healthy man can compensate readily for far greater changes; the regulation of temperature is disordered during pyrexia or, as some would maintain, is set at a new level. Pyrexia is only one sign of the complex response in metabolism to the invasion of micro-organisms, and the explanation of the course of the temperature in different fevers must be sought in the processes of infection and immunity. The micro-organisms not only produce different toxins, but they have a different life-history. The toxins circulating in the body produce a disturbance in the exchange of material and in the regulation of temperature; the response of the body to the presence of the toxin is the production of an antitoxin. The effect of the one may be antagonised by that of the other; the type of temperature may depend upon the relative production of each. The life-history of the micro-organism will affect the production of its toxin. Thus, in malaria the rise in the temperature of the patient coincides with the segmentation and sporulation of the parasite; in tertian ague this occurs every 48 hours, and in quartan ague every 72 hours. In relapsing fever a relationship has also been found. Further, this view is confirmed by the beneficial effect of those so-called antipyretics, which destroy the micro-organisms; quinine kills the malarial parasite and prevents the rise of temperature.

Difficulties in such explanations no doubt arise. The effects may not be constant in animals of different species, or in individuals of the same species; instead of a rise of temperature following the injection of the micro-organism or its toxin, there may be no effect or a fall in temperature below the normal. These are not fatal objections, for similar results are produced by simple drugs, and it is known that mixed infections may occur, for even in the healthy animal pathogenic organisms can be found.

Stages of fever.—Further progress will be made as the result of investigations upon the relationship of micro-organisms, toxins and antitoxins, to the different stages of pyrexia. Three stages are recognised: the initial stage, which may be accompanied by a definite *rigor*; the second stage, or *fastigium*, in which the height of the pyrexia is reached; and the third stage, or *defervescence*, in which the temperature falls by *crisis* or *lysis*. In the first stage the successful invasion by the micro-organism appears to have a stimulating effect upon the nervous control of the muscles, including the muscles of the cutaneous blood vessels; the result is shivering, a pallid contracted skin, known as "goose skin"; the temperature rises owing to increased production and diminished loss of heat. During the second stage the regulation is disturbed, but not paralysed, for the patient can respond to heat and cold, and shows a daily variation in his temperature; the disordered nervous

control is a part of the complex reaction in metabolism, the patient is fasting, and his reserves of carbohydrates having been consumed at an early stage he draws upon his nitrogenous materials as well as his fat. Apart from the inanition, the nitrogenous destruction may be due in part to the effect of the high temperature, which increases the general metabolism, and to some destructive action produced by the micro-organism or its toxin. The skin is flushed during the second stage, owing to the relaxation of the blood vessels, but in many cases the sweat glands appear to be paralysed as a part of the general toxic effect of the infection upon the secretory and excretory glands; the loss of heat is not sufficient to compensate for the increased production, the pyrexia is maintained. The rashes characteristic of certain infections are related probably to the toxins or other substances produced by the bacteria, or the cells of the tissues attacked.

In the final stage the action of the micro-organism or its toxin appears to be neutralised by the various protective mechanisms of the body, such as antitoxins; the loss of heat is greatly increased by profuse sweating, the temperature falls and with it the abnormal production of heat caused by the rise above the optimum temperature. The vicious circle is broken. The contest is over.

Significance of fever.—The pyrexia appears to be an essential part of the defence, for experiments show that recovery from infection is aided by a high temperature, and micro-organisms, even if they are not killed, may have their virulence attenuated by the high temperature. The rise of temperature produces increased metabolic changes, and some of these are of a special kind, and may be necessary for the formation of protective substances. Experiments have shown that agglutinins and bacteriolytic substances are produced more quickly and abundantly in infected animals kept at a high temperature than in similar animals kept at ordinary temperatures for the purpose of control. If the pyrexia be beneficial, how are the good results of the remedies which combat the high temperature to be explained? Quinine destroys the malarial parasite; its beneficial effect is not due to the reduction of the temperature. The cold water treatment of fevers has other effects besides the reduction of temperature, for it is recognised now that the skin, the largest organ for the reception of stimuli, has a great effect upon the nervous system and through it upon all parts of the body; the improvement produced by sponging the body is often out of proportion to the reduction of temperature. The mortality from fevers in man does not, as statistics indicate, depend upon the height of the temperature, and physicians have recognised that serious dangers may arise from the use of some antipyretic drugs. In the struggle for existence the body has evolved its protective mechanisms, and among these must be placed pyrexia as a part of the response to the invasion of micro-organisms.

The regulation of temperature and the factors which disturb it have been considered in detail, because there is considerable neglect of the subject, and a widespread tendency to describe as "fever" or "pyrexia" every rise of temperature in man above 100°·4 F. (38° C.). *Fever is a response in metabolism to the invasion of micro-organisms and a toxic disturbance of the nervous regulation of temperature.* It is possible for fever to be accompanied by no rise of temperature, and this is recognised clinically as "apyrexial fever" or "non-febrile fever"; such a condition is seen especially in in-

fections occurring in old and feeble subjects. The high temperatures often observed in lesions of the central nervous system at the onset have no relation to infection, and confusion only results if the hyperthermia is regarded as fever. The same remarks apply to heat-stroke.

The effects of fever on the various systems.—These may be mentioned briefly, in so far as they are common to the various infections.

1. *Metabolism.*—A characteristic feature is the increased katabolic or destructive phase of the metabolism, or exchange of material in the body. The destruction of protein is abnormally great, as proved by the increased output of nitrogenous substances in the urine, the wasting and loss of weight of the patient. This is doubtless in part explained by the inanition, due to the loss of appetite and diminished consumption of food. Other factors, however, are concerned, for a fevered patient loses nitrogen more rapidly than a healthy man who is starving. The rise in temperature increases the destructive changes, and the toxins of the infections, which may be compared with those in malignant disease, produce a similar effect. These changes are shown by the large amounts of creatinin and purine bodies in the urine during pyrexia and the increased excretion of urea during the crisis. The balance of water and salts is disturbed, there is a decrease in sodium chloride in the urine during pyrexia, and owing to the imperfect oxidation of fat acidosis is produced. At present little is known upon these points; life depends upon the adjustment of variations, one extreme produces "water poisoning," the other "salt poisoning."

2. *Secretion and excretion.*—The diminished activity of the alimentary system appears to be the resultant of the combined effects of the toxins, inanition and high temperature. In some infections there may be actual damage to the glandular tissues, such as occurs in the kidneys in scarlet fever. In the absence of such direct action, the albumin and albumoses present in the febrile urine are probably due to the abnormal destruction of protein in the body, the high temperature and circulatory disturbance.

In many cases the sweat glands appear to be paralysed by the toxins, for as a general rule sweating is absent during the rigor and fastigium, but abundant during defervescence. In rheumatic fever and acute miliary tuberculosis sweating is present during the fastigium.

It is known that the glands of internal secretion influence the production and loss of heat, but the part which they may play during pyrexia still requires clear demonstration by observation and experiment.

3. *Respiration.*—The cause of the increase in the rate of respiration observed during fever is to be sought in the high temperature and chemical changes in the composition of the blood supplying the respiratory centre in the medulla oblongata. An increase in the gaseous exchange is evidence of increased production of heat; in tuberculosis, typhoid fever and malaria percentage increases of 32, 48 and 60 respectively above the normal have been observed.

4. *Circulation.*—The regulation of the circulation of the blood is disturbed by the high temperature, inanition, and the toxic substances which affect not only the nervous control but also the tissues of the heart and blood vessels. The heart is very susceptible to a rise of temperature and malnutrition, and there is evidence of toxic action in the cardiac failure which may occur in diphtheria. In recent times special attention has been directed

to the impaired condition of the heart after an attack of influenza ; the injury appears to bear no direct relationship to the height of the pyrexia. The blood pressure is generally raised during the onset of a fever, when the cutaneous arterioles are contracted and the heart is beating rapidly ; later, when the blood vessels dilate and the heart beats less strongly, the blood pressure falls and the pulse becomes dicrotic.

5. *Nervous system*.—The disturbance of the nervous system is shown by the restlessness, depression and general vague sensations of “feeling unwell.” Delirium is common, especially in the evening when the temperature is generally higher. The causes appear to be the drug-like action of the toxin and the rise of temperature.

Treatment.—If the foregoing general account of fever represents the balance of evidence, it is obvious that an analysis of the causes in each case must be the guide for treatment. A rise in temperature is no proof of fever, for muscular work will produce a rise to 101° or 102° F. (38°·33 to 38°·89 C.) in perfectly healthy men ; a failure to recognise this physiological hyperthermia appears to be responsible for the retardation of the recovery of many patients suffering from tuberculosis. It is true that such patients react unduly to muscular work, especially if there be active disease, but it is equally true that prolonged rest in bed will diminish the capacity and resistance of a healthy man.

The abnormally high temperature in cases of heat-stroke is not hyperpyrexial in the strict sense, for there is no satisfactory evidence of infection ; the condition can be produced by exposure of healthy men or animals to a high temperature when the air is moist and especially when muscular work is performed. Treatment by drugs is useless, whereas the external and internal application of cold, by baths, cold packs or iced-water enemata have given excellent results.

In young children the regulation of temperature may be more easily disturbed than in adults, and a rise of temperature may be produced by trivial causes.

The routine treatment of fever by antipyretics is not justified by knowledge or results. The use of drugs which destroy the infective organism, such as quinine in malaria, can be defended, likewise that of vaccines and antitoxins, which increase the resistance of the patient.

The fever of tuberculosis will yield to those conditions, such as exposure in the open air and progressive muscular work, which increase the metabolism and resistance of the body to the infective organism. Antipyretics appear to be useless, for none is known to be specific, in the sense that quinine is for the malarial parasite. The evidence for the value of vaccines and antitoxins is given in detail elsewhere (see p. 24, *et seqq.*).

When delirium or other nervous disturbances are present, the best and safest treatment appears to be sponging with cold water, for it has been mentioned already that the skin is the largest nervous receptor in the body. The internal temperature may or may not be reduced much, but the temperature of the skin is. Even in perfectly healthy subjects, nervous inactivity and sleep cannot be obtained if the skin is too hot at night during a heat wave, or too cold in winter. It must be recognised that the tone of the peripheral blood vessels is influenced greatly by the temperature of the skin.

The thirst, which is a demand for water, should be fully satisfied by cold water or lemonade made from lemons. Although the skin may be dry owing to the absence of sweating there is an increased loss of moisture by the breath of the fevered patient, and the scanty and concentrated urine is evidence of a lack of water. There is no physiological reason for undue distrust of a patient's likes and dislikes; on the contrary, they are probably the expression of physiological needs. The desire for water and fruits appears to be a natural response to the needs for fluid, sugar and vegetable acids, which in the body will supply carbonates, assist the balance of water and salts, and mitigate acidosis.

In vigorous patients there appears to be no advantage in urging them to take food against their inclination, for the reserves of the body are adequate for a long fast. As a general rule the appetite is the best expression of the need for food. The mouth should be cleansed by a wet rag or by rinsing out with water, so that the excess of fur may be removed from the organs of taste, often covered with debris and dried by breathing through the mouth. Such simple attention and care will increase the enjoyment and digestion of food. On a fever diet a daily evacuation of the bowels is not to be expected and need not be produced by purgatives.

M. S. PEMBREY.

INFECTION

EFFECTS OF BACTERIAL ACTIVITY

When a bacterial invasion of the body tissues occurs the result is disease; the process is spoken of as an infection, and the bacterium is said to be pathogenic. Such a micro-organism, being capable of flourishing at body temperature, belongs to the parasitic group of bacteria. By no means all parasitic organisms are capable of pathogenicity, and, moreover, any one pathogenic micro-organism varies under changing conditions as to its pathogenicity for any particular animal, and may, while generally pathogenic to any one species, be incapable of infecting other species.

Again, micro-organisms that are potentially infective may and do exist under saprophytic conditions, that is to say, apart from the animal body, and under different conditions as regards temperature, etc. Saprophytic bacteria that are incapable of invading living animal tissues may yet invade the animal body when any part thereof is so injured as to be dead, or is in process of dying, and by proteolytic destruction of such dead tissue may elaborate substances called ptomaines, which substances are poisons capable of bringing about the death of the host. Ptomaines are analogous to alkaloïds and are not destroyed by heat; and as they may be produced by the action of saprophytic organisms in diverse kinds of decaying animal and vegetable tissues, they account for a certain proportion of the cases of food poisoning produced by the eating of canned and tainted food products, but true ptomaine poisoning is rare.

Certain varieties of bacteria, usually infective, may become saprophytic. The hosts are then termed "carriers." The best known examples thereof are the typhoid bacillus, the diphtheria bacillus and the meningococcus.

The two former examples generally, if not always, occur after an infection, whereas the meningococcus is more often found existing in a saprophytic than in a pathogenic state. In these cases the bacteria do not exert any apparent harmful effect, but they are, of course, of great potential danger to the surrounding community.

A similar condition exists in connection with the paratyphoid bacilli and those of the food-poisoning group generally. In these cases, however, there are usually symptoms of a recurrent nature, such as more or less mild attacks of gastro-enteritis associated with malaise, which symptoms may recur over long periods of years. A history can frequently be elicited of the initial attack of fever associated with symptoms of enteritis. This condition differs to some slight extent from that of the carriers noted above, in that there is some evidence, continuous or recurrent, of constitutional disturbance, though in the periods between recurrence, which may be prolonged, the condition closely resembles that of a carrier. Whether the condition that determines a recurrence is one of increased virulence of the bacillus or decreased resistance of the host is not yet clear.

Infective bacteria are generally aerobic, or facultatively aerobic. True anaerobes have very little power of spreading through uninjured animal tissues unless they are accompanied by aerobes, though they may cause localised infections in tissues in which the oxygen supply is limited. Hence the bacteria usually associated with infections are aerobic organisms that flourish at body temperature.

It has been stated that a bacterium usually pathogenic may vary under different conditions. These conditions may pertain to the bacterium itself or to the animal infected. A microbe may belong to a highly infective variety and yet vary greatly in its infectivity. This property is known as virulence, and depends on various factors. Mere subculture in the laboratory usually lowers the virulence, markedly in the case of typhoid, and slightly or not at all in the case of Malta fever. Passage through an animal of similar species raises the virulence to that species, while usually lowering it towards members of different species. Growth under conditions other than the optimum—for instance, growth at lower or higher temperature or growth in the presence of antiseptics—tends to lower virulence.

The subject of virulence, however, presents many difficulties. For instance, in the case of anthrax, animals whose serum is markedly bactericidal to anthrax bacilli will succumb if quite small quantities of anthrax bacilli are injected. Bail, investigating this observation, brought forward the contention that certain bacteria when invading an animal elaborated an offensive substance which paralysed the protective powers of the host, chief of which would be phagocytosis. He termed this substance aggressin, and described experiments showing that sublethal doses of infective bacteria became lethal doses when aggressin was added. He also classified bacteria in relation to their powers of forming aggressin. His theories were, however, attacked by Wassermann, Citron and others, who showed that Bail's exudates might act in the way he claimed they did by reason of containing endotoxins, in that they paralleled his results by aqueous extracts of bacteria. Notwithstanding the doubtful position of the aggressin theory there seems to be some offensive mechanism differentiating virulent from avirulent bacteria, apart from such characteristics as the possession of capsules, and

not altogether explained by the inhibition of positive chemiotaxis by direct toxic action.

The *dose of infecting organisms* introduced is a matter of importance. Whereas one or two anthrax bacilli cause a fatal infection in a white mouse, a considerable quantity of even a virulent streptococcus may be necessary to cause an infection in a susceptible animal. The normal tissues are capable of dealing immediately with a certain quantity of even moderately virulent organisms.

The *path of infection* has an important bearing on the results of any given infection. Thus staphylococci injected subcutaneously in a rabbit produce a local abscess, while if the injection be intravenous, pyæmic abscesses may lead to death. Typhoid bacilli must be swallowed to be infective, while it has been demonstrated that plague may be caused by rubbing *B. pestis* into the skin.

Subject of infection.—Normal healthy individuals differ greatly in their reaction to infective microbes. They differ because of individual or racial characteristics, or because of environment or age. Many micro-organisms, for instance, that are pathogenic to man are non-pathogenic to the lower animals. Thus syphilis can be transmitted experimentally to the higher apes only, and leprosy is incapable of infecting any animal but man. The susceptibility of a given individual is increased by prolonged exposure, great fatigue and starvation, or any condition leading to a generally diminished vitality.

A *local susceptibility* may be brought about by trauma so injuring the part as to cause a loss of vitality by shock, or interference with the circulation, a condition which may by reason of deficiency of oxygen permit even anaerobic organisms to flourish. Trauma also may be the direct agency of introduction of large quantities of infective material into tissues which by the same action are rendered less resistant.

An existing disease or condition may modify the reaction of the host to an infection. Thus the subjects of diabetes are abnormally prone to staphylococcal and tuberculosis infections.

There is some evidence that the activity of an infecting micro-organism can disturb the normal relationship between the host and its saprophytic inhabitants. Thus in typhoid fever, symptoms occur which appear to be connected with abnormal activity of the bacilli of the intestinal coliform group. Also any chronic intestinal infection appears to conduce to an increase in the intestinal streptococcal flora. It is not uncommon to find in amœba-carriers or subjects recovered from amœbic dysentery a very marked profusion of intestinal streptococci, and this condition is occasionally noted as a sequel to paratyphoid and similar infections.

Bacteria that are capable of spreading in the tissues, when such tissues are not rendered abnormal by reason of trauma, shock or inhibition of circulation, or by reason of the existence of some such disease as diabetes, usually have the power of causing *septicæmia*, that is, of flourishing in the blood stream, and, as a sequel, have the power of producing pyæmic infective processes.

Other bacteria causing acute infections do at certain stages of the infection appear in the blood stream, but at a later stage disappear therefrom, the *bacteriæmia* being incidental to, but not coextensive with, the infection. Thus streptococci and staphylococci and certain other bacteria may establish

themselves in the blood stream, and the resulting embolic abscesses may cause death; while in typhoid fever there is always a temporary bacteriæmia which tends to disappear before the termination of the disease, and only rarely causes localised abscesses, but is possibly responsible for the infection of the Peyer's patches.

The faculty of invading the blood stream comes under consideration when estimating the infectivity of such an organism as *M. catarrhalis*, which is never recovered from the blood stream, and, unlike the diphtheria bacillus, which also does not invade the blood stream, does not elaborate a soluble toxin. Important facts in connection with this faculty of invading the blood stream possessed by certain bacteria have been adduced by Wright. He showed, in connection with suppurating wounds, that whereas the discharge from a wound showed a very diverse flora, the fresh serum exuding into such a wound would only permit the growth of streptococci, and to a less extent staphylococci. These organisms in consequence he terms serophytes. He also showed that the fresh serum was more antitryptic than the wound discharge, and attributed the lessened antitryptic value of the discharge to trypsin set free by leucocytolysis. The diverse varieties of bacteria able to flourish in the tryptic discharge he termed serosaprophytes. It will be noticed that the serophytes correspond to those bacteria most likely to be found in cases of septicæmias.

RESULTS OF BACTERIAL INFECTION

Having thus briefly considered the relationship between the animal and human organism and infective bacteria, we pass on to trace the results of bacterial invasion.

If the individual be in a normal state of health, even a large quantity of virulent micro-organisms can gain admission to his body, and owing to the local defences may be destroyed before damage occurs; such a repelled invasion causes no symptoms, and the subject thereof will remain unconscious of it.

Or a local engagement of greater magnitude may ensue, resulting in an abscess, or a condition of cellulitis, or chronic suppuration. While, again, if the local defences prove insufficient a general infection occurs which is spoken of as septicæmia or bacteriæmia, or according to the nature of the infecting organism a diffusion of pyæmic abscesses may occur.

If the process remains a localised one the only effects may be a greater or less amount of necrosis of the tissues in that region, the ultimate defect depending upon the importance of the tissues in question. On the other hand a greater or less degree of general poisoning may occur by reason of soluble poisons liberated from the bacteria. These poisons are termed toxins.

TOXINS are of two varieties, exotoxins and endotoxins.

Exotoxins are soluble poisons elaborated by certain classes of bacteria—notably diphtheria and tetanus—and recoverable from the medium in which these bacteria have grown, without the death of the elaborating microbes having necessarily occurred.

Endotoxins, on the other hand, cannot be recovered separate from their elaborating microbes. This means that those bacteria which only elaborate

endotoxins can only poison an animal organism by proliferating within that organism, while the poisoning produced by exotoxin may occur without the actual invasion of the body by the elaborating organism.

Inasmuch as autolysed cultures of endotoxin-forming bacteria give toxic filtrates, owing to the solution of the bacterial substance, it is not easy to differentiate between true toxins, the exotoxins of organisms like diphtheria and tetanus, and the endotoxins. The ultimate differentiation rests upon the fact that the injection of soluble toxin into an animal calls forth a response of an antibody—antitoxin, whereas the injection of the solution of endotoxin though calling forth a response of antibody does not induce the elaboration of antitoxin.

Incidentally it may be here remarked that the difference between exotoxin and endotoxin is a fundamental one in specific therapy, as in a toxæmia from exotoxin a suitable antitoxin in appropriate amount constitutes an adequate defence, while in the case of toxæmia from an endotoxin the elaborating bacterium itself has to be proceeded against, and this most often necessitates the use of a vaccine prepared from the bacteria involved.

The mode of action of toxins is very variable and depends upon the variety of bacterium. The true toxins of diphtheria and tetanus tend to produce profound poisoning effects on the nerve tissues. Thus the ingestion of sufficient diphtheria toxin leads to paralysis notably of the soft palate; but according to the size or virulence of the dose, or condition of the subject, all the voluntary muscles of the body may become paralysed. Tetanus toxin is selective to the cells of the central nervous system, chiefly those of the motor areas, leading to a condition of tonic spasm.

The toxins associated with other acute and chronic infections produce various effects, prominently fever and degeneration of muscle tissue, such as the heart muscle in pneumonia and influenza. The toxins produced as the result of streptococcal activity have a wide range of effect. Thus in acute infections the heart muscle suffers specially as well as the synovial membranes of joints, while in chronic streptococcal infections, such as pyorrhœa alveolaris, a general fibrosis of connective tissue may occur, leading to arthritis and involving the bony and connective tissues of joints, and fibrositis generally. Associated with these changes there is frequently marked mental depression, which is possibly a direct effect of the toxin on the nervous system.

JOHN MATTHEWS.

THOMAS HORDER.

IMMUNITY

Definition.—Immunity is that function of the animal organism by virtue of which the effects of bacterial activity are resisted.

Immunity is either natural or acquired.

NATURAL IMMUNITY

Many diseases commonly infecting man do not spontaneously occur in animals, and conversely many animal diseases do not spontaneously affect man. Experimentally a naturally immune animal may be infected; thus the

chimpanzee can be infected with syphilis. These experimental infections of naturally immune animals are usually, however, of a mild character. Moreover, different species of animals show great variability in immunity. For instance, rats and dogs are immune to anthrax. The factors determining these differences of immunity are not well understood, but variations in diet, as between carnivora and herbivora, the environment and habits, and variations in physiological metabolism partly account for them. There are also degrees of natural immunity in the different races of man. Thus the natives of countries where certain diseases are endemic may be far more resistant to those diseases than inhabitants of countries where the diseases are not endemic, as shown by the resistance of the negro to yellow fever. Conversely, diseases that have existed for years endemically among one race or group of races may cause a veritable plague when introduced to a fresh race. Thus tuberculosis ravaged the North American Indians, and syphilis when introduced to Europe from America, where it was probably endemic, followed the course of an epidemic of a highly contagious disease.

These racial types of immunity, however, are to some extent acquired, either by constant exposure of individuals to contagion, or by survival of the fittest.

As regards the mechanism of natural immunity there might be two explanations. One, that naturally immune animals were resistant to the bacteria themselves, and the other, that they were resistant to the toxins of the bacteria—in other words, that the bacteria possessed the power of invading the animal, but that the invasion had no toxic effects. As a matter of fact, naturally immune animals possess the power of resisting the invasion of bacteria, and the resistance seems to be a function of phagocytosis, as the phagocytic power of naturally immune animals varies according to their immunity, whereas the bactericidal action of their serum does not vary in this direct relationship. Nevertheless phagocytic activity depends largely upon substances in the serum, as will be shown later.

There is also individual immunity, as shown by the fact that in any epidemic some individuals entirely escape infection, while in those infected all degrees of resistance are noted.

In contradistinction to individual natural immunity, which condition does not lend itself to analysis, there is the condition of individual susceptibility—a condition to which considerable study has been devoted, chiefly in the direction of non-bacterial toxæmias such as hay fever and the various toxic idiopathies. Possibly, however, the various manifestations of the rheumatic state are destined to be grouped under a condition of individually decreased resistance to the endotoxins of streptococci.

There is a tendency, specially among American writers, to range all the phenomena of the toxic idiopathies under anaphylaxis.

The outlines of immunity which have been hitherto considered have chiefly been concerned with the reactions between bacteria and the body fluids, and together with further principles in connection with toxins and anti-toxins, which will be studied later (p. 19), were in the main formulated by the German school of bacteriologists, especially Ehrlich and Pfeiffer.

The theory of immunity elaborated by this school was termed the Humoral Theory.

Phagocytosis.—Concurrently with the elaboration of this theory, however,

Metchnikoff's school was bringing to light many important facts in connection with the action of bacteria upon the cellular elements of the body. And Metchnikoff, holding the view that phagocytosis was the essential principle in immunity, formulated the Cellular Theory. The facts on which this theory was founded are briefly as follows: Amongst the lowest unicellular animals nutrition takes place by the ingestion of particles, those unsuitable for nutrition being extruded, while suitable ones become surrounded by a vacuole and, by the aid of a proteolytic ferment, digested.

Ascending the animal scale this function of ingestion becomes limited to special groups of cells, and in the higher animals to a still more circumscribed group of cells, the phagocytes. Moreover, the function itself ceases to be of nutritional benefit to the animal, but becomes specialised to the service of immunity.

Phagocytes are divided into two groups—microphages, comprising the polymorpho-nuclear leucocytes, and macrophages, including the endothelial cells lining the serous cavities, blood and lymph vessels, and the large mono-nuclear lymphocytes.

The microphages are chiefly concerned with phagocytosis of bacteria, while foreign cells or impaired cells of the animal host, as well as animal parasites, are accounted for by the macrophages.

A local infection of staphylococci, or the injection into the body of staphylococci, or even nutrient broth, at first causes a diminution in the number of leucocytes locally, but quickly a great increase of phagocytes occurs. This phenomenon is termed positive chemiotaxis. The degree of chemiotaxis varies greatly according to the variety or virulence of the bacterium involved, and there may be a definite repellent action which is termed negative chemiotaxis. The exact mechanism of the phenomenon is not well understood. There is, however, a definite relationship between positive chemiotaxis and phagocytosis, apart from the fact that unless positive chemiotaxis exists phagocytosis cannot take place. And though positive chemiotaxis varies to some extent inversely with virulence, yet virulent and living organisms may be phagocyted. Phagocytosis is preparatory to digestion, though the facility with which organisms are digested varies greatly; some, such as anthrax and tubercle bacilli, being very resistant to digestion though easily phagocyted.

It was shown by Metchnikoff that there was a direct relationship between the development of immunity in an artificially immunised animal and the phagocytosis of its white cells. As the result of a vast amount of experimental work, Metchnikoff claimed that phagocytosis was the fundamental factor in immunity, while Pfeiffer and the German school claimed that the important factors of immunity pertained to the anti-substances elaborated in the blood fluids and serous exudates, and that the phagocytes were simply concerned with scavenging duties in connection with the dead or dying bacteria, damaged by the action of specific antibodies elaborated in the serum.

It must be noted that Metchnikoff recognised the existence of these antibodies, but claimed that they were derivatives of leucocytes; and his later contention was that the immune substance in the serum acted directly upon the leucocytes, and, indeed, he used the term "stimulin" to denote that substance.

This view was opposed by Denys and Leclef in 1895, who suggested that the immune principle acted upon the bacteria.

The controversy was carried a step further as the result of the researches of Wright and Douglas in 1904 and 1905. They showed that washed corpuscles, *i.e.* leucocytes deprived of serum, had a very slight phagocytic effect on bacteria, but that when a mixture of washed corpuscles, bacterial emulsion and normal serum was incubated, phagocytosis took place, whereas if the normal serum had been previously heated to 55° C. no phagocytosis occurred. Moreover, if a mixture of normal serum and bacterial emulsion were incubated, and the bacteria freed from serum were added to washed corpuscles, phagocytosis occurred freely. They called this thermolabile substance opsonin (*ὀψωνίω*, to prepare victuals).

By showing that the washed leucocytes of highly immunised animals had no more phagocytic powers than those of a normal animal, they effectively disposed of Metchnikoff's stimulin theory, supplanting it by the Opsonic Theory, founded on their discovery that opsonin, the immune principle on which phagocytosis depends, acts on the bacteria alone, preparing them for ingestion by the phagocytes.

Shortly after, Neufeld and Rimpau drew attention to an immune principle they termed bacteriotropin, differing from opsonin in that the former is thermostable. It was suggested that normal opsonin differed from bacteriotropin—immune opsonin; and various workers, Dean, Muir and Martin, have claimed that immune opsonin has all the reactions of immune substance or amboceptor.

Wright and Douglas showed that opsonin was increased in amount by active immunisation; and Wright suggests that the difference between normal and immune opsonin is merely one of quantity, and, in that opsonin may be only relatively thermolabile, a certain amount may survive heating.

The specificity of opsonin was shown by Bullock and others by means of absorption experiments.

However interesting, theoretically, the exact classification of opsonins may be with reference to other immune bodies, the practical outcome of Wright's discovery has achieved far-reaching results. Wright and Douglas demonstrated that the quantitative estimation of the opsonin content of any serum, in respect to any particular organism, was possible by comparing the phagocytosis occurring in a mixture of definite volumes of homologous bacterial emulsion, washed corpuscles and, respectively, normal serum and the serum in question. The measure of phagocytosis achieved in the serum under observation, divided by the phagocytosis of the normal serum, which latter is taken as unity, is termed the Opsonic Index.

In skilled hands the accuracy of the opsonic index, within the limits of experimental error, is very exact. Thus the index of a normal person to tubercle bacillus, or staphylococcus, rarely falls outside a measurement of between 0.8 and 1.2, whereas much greater variations are commonly found in the serum of individuals infected with either of these organisms.

It is obvious that in connection with those organisms which undergo bacteriolysis with immune serum the estimation of the opsonic index is at the best unreliable, as it also is with certain organisms which when in virulent condition are refractory to phagocytosis.

At the present time the practical application of the opsonic index is

chiefly directed to the detection of rapid changes in the amount of opsonin in connection with vaccine inoculations, to measure the effect of treatment, or with passive congestion experiments undertaken with a view to diagnosis.

The opsonic index of an infected individual to the organism causing the infection varies within wide limits. If a suitable staphylococcal inoculation be made, the initial result of the injection is a fall in the opsonic index corresponding to a fall in resistance, called by Wright the negative phase. After a brief period the index is found to be rising, corresponding to a rise in the resisting power, called the positive phase. The positive phase tends to last a considerable time in a non-infected individual, but is more or less transient in an infected patient. The object of vaccine therapy is to achieve the maximum of positive phases compatible with negligible negative phases. The amount of negative phase permissible depends upon the severity of the infection under treatment.

By bringing into application these principles, Wright elaborated the principles of vaccine therapy, which will be discussed under the heading of Immune Therapy.

ACQUIRED IMMUNITY

(i.) *As the result of recovery from infection*

When an individual has recovered from an acute infection such as typhoid fever it is a matter of common knowledge that he experiences immunity against that disease in future, so much so that the occurrence of a second attack is very rare. So also a second attack of scarlet fever, measles and the other exanthemata are unusual occurrences. This acquired immunity was recognised, but of course not understood, centuries ago, and history shows that attempts at protection were made by inoculating infective material; and it was on account of this knowledge, but with a fuller understanding thereof, that Pasteur commenced his study of protective inoculation that forms the basis of the modern knowledge of immunity.

Immunity acquired as the result of recovering from an infection varies greatly in different diseases, and in contrast with the lengthy immunity following recovery from typhoid fever and the exanthemata, the immunity following such a disease as pneumonia may be quite short. Indeed, there are those who say one attack of pneumonia predisposes to another.

It is doubtful if such an assertion is justifiable; and even if it were, it probably depends upon the fact that even successful recovery from acute pneumonia may still leave the individual a carrier of pneumococcus of modified but potential virulence.

(ii.) *Artificial Immunity; Active and Passive*

Pasteur in 1880 showed that injections of attenuated cultures of the organism of chicken cholera would protect the inoculated fowl against lethal doses of the virulent bacilli. From this observation resulted artificial

immunity, and because the protection is elaborated solely by the action of the tissues of the infected animal the term Active Immunisation was introduced by Ehrlich.

Von Behring in 1890 discovered that the serum of actively immunised animals when transferred to other animals conferred immunity on the latter, and this process is termed Passive Immunity. It differs broadly from active immunity in that the protection afforded is comparatively transient, depending as it does on the actual amount of immune substance introduced.

Active immunisation is the process underlying the whole practice of vaccine therapy, while passive immunisation is exploited in serum therapy. In the interests of clarity active immunity and vaccine therapy will be discussed in the first instance, and passive immunity and serum therapy will be considered later, but it must be understood that in point of time the basic principles and discoveries became available at more or less parallel periods, and though active immunity of necessity precedes passive immunity the principles of serum therapy were comparatively well understood before vaccine therapy was evolved as a general phylactic method.

Active immunity may be produced by the injection of—(1) living virulent bacteria; (2) living attenuated bacteria; (3) killed bacteria; (4) killed bacteria sensitised; (5) bacterial derivatives; and (6) active immunity can also be produced by feeding.

1. The injection of *living virulent bacteria* is accompanied by certain obvious disadvantages, and even where eventually, in order to obtain high degrees of resistance, such a method is advisable, it is usually preceded by the injection of attenuated or killed cultures.

2. *Attenuation of cultures* may be brought about by various means, such as growing bacteria in air or a current of oxygen, by growing them at abnormal temperatures or in the presence of weak antiseptics. The mere subculture of bacteria under laboratory conditions in many cases causes attenuation of virulence, while the passage of an organism through one species of animal usually attenuates its virulence for an animal of another species.

3. *The injection of killed cultures*.—This forms the fundamental process of the practice of vaccine therapy, and is also largely utilised in the production of specific sera for laboratory diagnostic methods, and specific anti-bacterial sera for the purposes of serum therapy in connection with those diseases in which an antitoxin is not indicated.

4. *The injection of killed sensitised cultures*.—This method was introduced by Besředka as a refinement. The bacteria are treated with an homologous anti-bacterial serum at body temperature. The serum is then separated. The antigenic properties of the vaccine produced are theoretically greatly diminished, in view of which the higher doses of such vaccine which can be given are by some considered to be of doubtful advantage.

5. *The injection of bacterial derivatives—filtrates of cultures—toxins*.—This process constitutes the basis of the manufacture of antitoxins, that is antisera for the treatment of diseases due to those bacteria which are harmful by reason of exotoxins—diphtheria and tetanus.

6. *Active immunity can be produced by feeding*.—Thus Ehrlich immunised

mice against ricin and abrin, and Frazer immunised rabbits against snake venom by feeding. The method, however, has not much practical application, otherwise a spontaneous cure of such a disease as pyorrhœa would be more evident.

Antitoxins.—We come now to the consideration of the immunity produced by the injection of bacterial filtrates to which the name toxins has been given. Injections of toxins call forth the production of anti-substances known by the name of Antitoxins, which figure last in our list of anti-substances; this position, however, is merely for the sake of convenience, for the study of antitoxin formation is particularly important as it was first in the point of time, and it furnished a great proportion of the principles constituting the present knowledge of immunity.

We have seen that bacteria fall into two groups—one which produces exotoxin, the other producing endotoxin. The exotoxin group, small in the point of numbers, comprising the diphtheria and tetanus bacilli, is important in that it furnishes almost the whole of the facts in connection with antitoxin formation.

As the result of the systematic use of diphtheria antitoxin the mortality of that disease has been estimated in a review of 50,000 cases to have decreased by 50 per cent.

For the production of a satisfactory antitoxin a powerful toxin is necessary. Less than 0·01 c.c. should be capable of killing a 250-grammes guinea-pig in 4 or 5 days.

Various methods of raising the virulence of bacteria have been alluded to, and they are brought into application in this connection. Horses have been found the most suitable animals in the process, and they should be sound as regards constitution, and of from 4 to 6 years of age.

Small initial doses of toxin, or toxin mixed with antiseptics or with antitoxin, are used; the doses being gradually increased until at the end of 2 or 3 months more than ten times the original dose may be given.

In favourable cases each cubic centimetre of horse serum may then contain up to 800 units of antitoxin.

A unit of antitoxin is that amount that will save the life of a guinea-pig if injected with 100 units of toxin, while the unit of toxin is that quantity sufficient to kill a guinea-pig of 250 grammes in from 4 to 5 days. Hence a unit of antitoxin is that quantity that suffices to save the life of a guinea-pig injected with 100 minimal lethal doses of toxin.

As antitoxin when evaporated to dryness is comparatively stable compared with toxin, such products form the standard, and are to be obtained from various institutions.

Ordinary antitoxin, however, will retain its potency for a year if kept in a dark, cool place.

Antitoxic sera produce their effects by simple combination with, and neutralisation of, the toxins eliciting them, in which their action differs from that of opsonins and agglutinins, in both of which instances visible and measurable effects are observable.

Much discussion has occurred as to the nature of their union. Ehrlich maintained there was firm chemical union; Arrhenius and Madsen considered the union similar to that of two substances in weak chemical union, a union to some extent reversible; while Bordet considered it was a physical

process, the smaller molecule of toxin becoming, as it were, entangled in the larger molecule of antitoxin. The union has a time factor, as shown by an experiment of Martin and Cherry, who forced toxin and antitoxin through filters under high pressure. At first all the toxin passed through, but after 2 hours no toxin passed, as it was held back by union with the antitoxin.

A great deal of work has also been done in connection with the question of the composition of toxin, but it must suffice to say that toxin represents more than one poisonous substance, and that the proportions vary in different samples. Similarly, the composition of antitoxin has been the subject of much discussion. That antitoxin is not merely altered toxin is certain in that antitoxin may be obtained in an amount many times greater than that of the toxin injected.

Normal horse serum may contain a certain amount of antitoxin to diphtheria, and probably high immunity to toxin represents merely an elaboration of a normal substance and not an entirely fresh product. It is, however, certain that antitoxin is the product of cellular activity.

Antitoxin substance probably belongs to the globulins, and it has been shown that, in general, highly immune sera contain more globulin than normal sera. This, in fact, is the only chemical difference that has been demonstrated between normal and highly immune sera.

Anti-bacterial sera.—In connection with cerebro-spinal meningitis much work has recently been done in reference to anti-meningococcus serum. A horse is injected with killed cultures of mixed strains and with autolysed cultures, and finally with living cultures. The result is an antiserum which contains immune bodies which bind complement, agglutinins and opsonins, and the presence of these substances is made use of in estimating the potency of the serum. There is also probably anti-endotoxin present, as Gordon has described a method of estimating the titre thereof.

As the result of intrathecal injections of the antiserum the meningococci in the cerebro-spinal fluid show a marked decrease, which decrease is thought to be due to increased phagocytosis, as owing to the absence of complement no direct bactericidal action can occur. Anti-meningococcus serum is thus in marked contrast to diphtheria or tetanus antitoxin, in that the effects of the former are chiefly directed against the bacteria and only partly against the endotoxin content of the bacteria.

Extensive use has been made of anti-streptococcal sera. They are prepared by injecting horses with, firstly, killed cultures and subsequently living bacteria. Marmorek increased the virulence of his streptococci by growing them alternately in the peritoneal cavity of a guinea-pig and in a mixture of human blood serum and broth. The potency of the serum was measured by mixing it with a certain quantity of virulent streptococci and injecting the mixture into a rabbit. Marmorek found, however, that the serum had little protective power as against filtrates of cultures.

Such occasional good effects as follow the use of anti-bacterial sera are explained by some authorities as being due to the antigenic action of the streptococcal substance contained in the serum, causing it to function as a vaccine, or to the anti-bacterial substances contained in normal horse serum.

Dysentery antisera which have lately come into use are apparently anti-bacterial and antitoxic.

THE PROPERTIES OF IMMUNE SERA

Von Behring's discovery that the sera of immune animals could passively confer immunity shows that such immune sera contain substances either different from those, or in excess of those, present in normal sera; and in 1894 Pfeiffer showed that if cholera spirilla were injected into the peritoneal cavity of a highly immunised guinea-pig, the bacilli lost motility, became granular and swollen and finally disappeared. This phenomenon became known as Pfeiffer's phenomenon, or Bacteriolysis.

It was then shown by Metchnikoff and Bordet that a similar result occurred *in vitro* in a mixture of heated immune serum and cholera vibrios if, and only if, normal serum be added. As result of these and subsequent researches it was recognised that two substances are present in immune sera, one of which is peculiar to immune and the other common to immune and normal sera. The former, originally called "substance sensibilisatrice" (Bordet), is now generally known as *amboceptor* (Ehrlich); while the latter, formerly called alexin by French writers, is now usually known as *complement* (Ehrlich).

It will be recognised from Metchnikoff's and Bordet's experiment alluded to above that the former resists heating, while the latter, destroyed by heating, was again supplied by the addition of normal serum. As a matter of fact, amboceptor resists a temperature of 70° C. for one hour, while complement is destroyed by a temperature of 60° C. for 10 minutes. The amount of complement in any serum is apparently not affected by immunity.

It will also be recognised that the specific change that has occurred in an immune serum is the presence of amboceptor, which can only act in the presence of complement. Amboceptor is specific in that it only acts in connection with the bacterium or inoculating substance which calls it forth (antigen), while complement acts independently and in connection with amboceptor of any kind.

Bacteriolysis also occurs in connection with typhoid immune sera, but many other varieties of bacteria are not subject to it; it can, however, be demonstrated that those organisms, immunity against which is unaccompanied by bacteriolysis, are susceptible to other properties of immune sera.

In connection, however, with bacteriolysis must be mentioned hæmolysis. Bordet in 1898 showed that if an animal be immunised with the serum of another species the serum of the immune animal acquires the property of destroying the red corpuscles of that species. This phenomenon of hæmolysis has become of great importance, as it forms the indicating phenomenon in the complement deviation test of Bordet and Gengou, and of its modification the Wassermann reaction.

Similarly many other cytotoxic sera can be elaborated by injecting emulsions of appropriate cells. Thus Metchnikoff produced a cytotoxic serum capable of destroying spermatozoa, by injecting spermatozoa; and such cytotoxic sera as leucotoxin, neurotoxin and others have been made. Inasmuch as most of them are also hæmolytic, their effects on the homologous organs are difficult of estimation, and their use is not of practical importance.

Agglutinins.—When a small quantity of immune serum is added to an emulsion of the corresponding bacterium, the organisms become agglutinated. If the organisms are motile they simultaneously lose motility. The phenomenon is most familiar in connection with typhoid and paratyphoid fevers, but can be experimentally observed in connection with all immune sera and their corresponding organisms.

In connection with typhoid fever Widal first published the observation that agglutination was observable shortly after infection took place, and increased as the disease progressed according to the degree of immunity achieved.

In practice it is usually sufficiently marked by the tenth day of the disease to enable a positive diagnosis to be made.

The physics of the phenomenon are as yet imperfectly understood. Agglutination occurs in connection with non-motile as well as with motile organisms, though it is most marked in the case of the latter. It also occurs with bacterial substance which is precipitated when the corresponding immune serum is added. A correct salt content of the solutions is necessary for agglutination as shown by Bordet, who resolved clumps of agglutinated bacilli by washing in distilled water and found the bacilli agglutinated again when salt was added.

It has been suggested that some analogous factor to surface tension may be involved.

Agglutinins are not destroyed at 55° C. as are bacteriolysins and opsonins.

Precipitins.—Krause gave the name of precipitin to the substance which produced the precipitate when an immune serum was added to filtrates of bacterial cultures. The phenomenon is closely allied to agglutination, and is by many authorities considered identical. As a method of diagnosis in bacterial infections it is not so useful as agglutination, but it has been highly developed by Nuttall, who has shown that when one animal is highly immunised against the serum of another animal a precipitin is produced in the serum of the former that will cause precipitation in the serum of the latter. With an appropriate rabbit serum highly immunised to human serum minute traces of human serum may be definitely identified.

Opsonins.—These substances have been already referred to in detail (see p. 17).

Anaphylaxis.—When a foreign protein is introduced into an animal hyper-susceptibility may be produced, which hyper-susceptibility can be demonstrated by injecting after the lapse of ten days a further—in itself non-lethal—dose of the protein, when there occurs a condition varying from slight signs of illness ranging through various stages of respiratory distress up to sudden death.

This constitutes anaphylaxis. The condition may be brought about by vegetable as well as animal proteins, and it is said by bacterial proteins. Most study has, however, been directed to the anaphylaxis produced in suitable animals—preferably guinea-pigs—by the serum of an animal of another species.

Originally compelling attention during antitoxin experiments, it was thought to have some connection with the action of the toxin, but it was soon recognised that the reaction had no relationship to the toxin or anti-

toxin content of the serum but was concerned only with the horse serum as being a foreign protein.

The anaphylactic state may be transferred by injecting a second animal with serum from an anaphylactic animal (passive anaphylaxis), and may be transferred from mother to offspring.

It has been claimed that the tuberculin and mallein reactions are anaphylactic phenomena, but it is difficult to understand why such reactions are universal in infected individuals, as it might be expected that desensitisation would be a frequent natural occurrence owing to repeated small doses of bacterial substance. Similarly the phenomena known as serum sickness following the injection of diphtheria antitoxin have been ascribed to anaphylaxis, but many of these cases may be due to a toxic idiopathy to horse serum and not to anaphylaxis.

It is, however, certain that a second injection of antitoxin after a sufficient interval may produce anaphylaxis. In consequence of this the question of desensitisation becomes of great importance. If at some period more than 10 days after an injection of antitoxin it is desired to give a further dose the presence of the anaphylactic state should be negatived. This is done by a skin reaction. A small quantity, say 0.25 c.c., of normal horse serum (or antitoxin) is injected intradermally, or rubbed into a scarified surface. There occurs, if anaphylaxis—or a toxic idiopathy to horse substance—exists an urticarial patch sometimes progressing to a vesicular eruption with a surrounding area of erythema.

This usually occurs within half an hour, but is occasionally delayed. If anaphylaxis be demonstrated the patient should be desensitised. If time be not of paramount importance, 0.025 c.c. of antitoxin is given subcutaneously and the amount is doubled every half an hour. After 1 c.c. has been given subsequent doses are given intravenously until 25 c.c. in all have been administered. If any anaphylactic symptoms occur, longer intervals and more cautious increments are indicated.

JOHN MATTHEWS.
THOMAS HORDER.

IMMUNE THERAPY

(A) GENERAL

NON-SPECIFIC AND SPECIFIC THERAPY

Two sorts of therapeutic measures may be employed in the control of diseases due to microbic infection—(1) measures that can be used to assist the patient's general functions (nervous, circulatory, respiratory, digestive and eliminative) during the extra strain which is being put upon them; and (2) measures that can be attempted in order to give help to the special function, or mechanism, of immunity against the particular infection. Treatment coming under the first of these heads is termed non-specific; treatment coming under the second head is termed specific. In regard to their degree of relative theoretical importance it is clear that specific measures should take precedence. But in practice dependence in a good many diseases may have to be placed entirely upon non-specific measures because, as yet, specific

measures are not available. The absence of available remedies for immune therapy may depend upon absence of exact knowledge of the causative agent in the disease or, this knowledge not lacking, absence of a sufficiently convincing or potent means of stimulating immunity or of supplying ready-made immune substances.

Whether immune therapy is practicable or not, it is of fundamental importance that no effort be relaxed in regard to the employment of accredited non-specific measures, and the use of these at as early a moment as possible in the disease. It behoves the practitioner to be just as prompt, and to be just as thorough, in the exercise of the various means by which a patient's general resistance to infection can be kept at a high level, as to be prompt and thorough in the use of any specific remedy that may have experience or experiment, or both, to recommend it.

AVAILABLE REMEDIES IN IMMUNE THERAPY

A study of the preceding articles upon infection and immunity will have made clear the methods by which resistance to microbic infection can be helped along specific lines. The actual substances that are available for this purpose, and which are in actual practice to-day, may be summarised as follows:

A. IMMUNE SERA.—(a) Antitoxin sera, which act chiefly by neutralisation of exotoxin formed by bacteria in the body. (b) Anti-bacterial sera, which act chiefly by destruction of the bacteria and thereby preventing the increase of endotoxin.

B. BACTERIAL VACCINES, which serve to stimulate the natural mechanism of immunity.—(a) Ordinary vaccines. (b) "Sensitised" vaccines. (c) "Live" vaccines. (d) "Phylacogens." (e) "Detoxicated" vaccines.

Some general comments will now be made concerning these various substances.

A. (a) *Antitoxin sera* remain the most strikingly successful, as they are historically the earliest of all the remedies used in specific therapy; and this applies especially to *anti-diphtheria* serum; less so to *anti-tetanus* serum, but the more limited success of the latter remedy is undoubtedly due to the difficulty entailed by the path of infection of the virus rather than to lack of potency in the serum. Given at the earliest possible moment, given liberally, and given by the intrathecal route as well as by the subcutaneous, the results are frequently very encouraging. Of the prophylactic value of this serum no doubt can be held after the experiences of the Great War.

(b) *Anti-bacterial sera* have never yet attained anything like the same degree of success as antitoxin sera. By none of the methods yet employed have these sera been produced with a sufficiently rich content of antibody to lead to any uniformly good results. A difficulty connected with the preparation of these sera is the fact that most of the bacteria against which they are manufactured exist in groups, and a serum prepared against one group is by no means specific in respect of antibody for another group.

The attempt made in the case of streptococci to produce "multivalent" serum to overcome this difficulty has not proved successful. More hope appears to lie along the line of producing univalent sera against the different groups. In the case of streptococcus infections a univalent *S. pyogenes* serum has been available for some years, as the result of suggestions put forward by Andrewes and Horder.

Cole's grouping of the pneumococci, and Gordon's grouping of the meningococci, have quite recently enabled serum manufacturers to produce sera for the different groups of these micro-organisms, and, in the case of the meningococcus, the use of these group-sera may possibly re-establish the reputation which anti-meningococcus serum obtained in the New York epidemic, and which it failed to retain in Great Britain.

Since the introduction of specific inoculation in the treatment of bacterial infections antisera have, with many workers, fallen largely into disuse. The production of "group-sera" may lead to results of so much better value that this type of remedy will be found to be once more in demand.

B. (a) *Ordinary vaccines*.—The earliest form of vaccine remains the one in most common use—a simple suspension of the killed microbe in normal salt solution. Most immunologists kill the bacterial elements by heat. Some prefer the system known as autolysis—allowing the micro-organism to undergo auto-digestion in the warm incubator after counting. Others rely upon a sufficiency of some such antiseptic as tricresol, believing that heat interferes with the efficacy of the vaccine. *If we knew exactly what are the initial processes going on in the human body when living microbes invade it we should be better able to decide how best to prepare the cell-element before we inject it in the form of a vaccine.* It seems reasonable to suppose that undue heat, and the presence of chemical agents, are both of them to be avoided if the tissue is to digest the bacterial cell as the preliminary step in the process of active immunisation.

(b) "*Sensitised*" vaccines ("sero-vaccines") are made by bringing a bacterial emulsion into contact with the appropriate immune serum (e.g., a *Streptococcus pyogenes* is mixed with a univalent *S. pyogenes* serum). The specific antibody in the serum becomes "fixed" by the bacteria, and the combination is termed a sensitised vaccine. There is considerable doubt whether this "sensitisation" of the vaccine actually takes place, and whether, therefore, its therapeutic value is in any way enhanced. Much must depend upon being able to secure a potent serum for the process, and we possess as yet very little guidance as to the amount of antibody present in a serum. The type of case in which sensitised vaccines have seemed to promise good results has been acute and generalised infection, especially by streptococci. The dosage of sensitised vaccines is 10 to 20 times that of the unsensitised material.

(c) "*Live*" vaccine has been used by Alcock and others; in some cases of gonococcus infection, and in one or two other infections. No special results appear to have been obtained—certainly none which counterbalance the obvious risks that might be run if such a system became generally adopted. The vaccines must be given intravenously, and there are reasons for regarding this route as less serviceable than the more solid tissues for vaccine introduction.

(d) The substances termed "*phylacogens*" come next under consideration. In the preparation of these substances the makers have made an effort to prepare the cell-body, which constitutes the essential part of the vaccine material, for easy assimilation by the tissues into which it is injected. This is obviously a move in the right direction. They argue, and pertinently, that valuable time may be lost during these preliminary efforts on the part of the tissues at digesting or disintegrating the bacterial cell-element in order to start the specific interaction that shall result in the formation of antibody. They therefore endeavour, partly by appropriate temperatures and partly by chemical agency, to get the bacterial cell-structure into solution. During this process there is inevitably added to the solution a certain amount of exotoxin, an amount depending, no doubt, upon the nature of the medium in which the bacteria are grown. But as this medium is invariably a fluid one, the amount of exotoxin cannot be negligible. This exotoxin, perhaps accounts for the very sharp reaction sometimes seen after the use of this class of remedy. It is possible that some of these reactions are of the nature of "protein shock." On general principles, seeing that the object in view is certainly not to add more exotoxin to the patient's burden, this feature must be regarded as undesirable. To what extent the endotoxin of the bacterial cell goes into solution it is not possible to say, because unfortunately we have no chemical means of measuring this substance; but it seems fairly certain that in the preparation of phylacogens a more successful effort has been made in this direction than hitherto.

No doubt the most valuable constituents in a phylacogen solution are the products of disintegration or autolysis of the cell-body other than endotoxin—substances which are capable of stimulating the formation of antibody possessing specific properties of service in the destruction of living bacteria. It is obvious, therefore, that phylacogens are extremely complex in their composition; they contain a certain amount of exotoxin, some endotoxin, the products of autolysis of the bacterial cell-body, and a little antiseptic. With such a mixture it must be extremely difficult to produce anything like a uniform solution, and it must be equally difficult to decide upon appropriate dosage. But the complication does not end here. There is introduced into the preparation of phylacogens another principle, altogether independent of that which attempts at securing solution of the antigen contained in the body of the bacterium. Considering every infection to be a mixed and not a single one, the manufacturers prepare what is termed a "mixed infection case," a solution in which the above-mentioned ingredients are derived from staphylococci, streptococci, *B. pyocyaneus*, *Diplococcus pneumoniae*, *B. coli*, *B. diphtheriae*, and the streptococci associated with rheumatism and erysipelas. Fifty per cent. of this basic phylacogen is added to each of the specific phylacogens during its preparation. Even though the general principle of mixed infections may have much to support it, it seems of doubtful value to load the tissues of a patient suffering, say, from typhoid fever, with toxins of the diphtheria bacillus and *S. erysipelatosus*. Too much has probably been attempted in the hope of producing a substance that will be of general, rather than of particular, service.

(e) The most modern of all the remedies of the bacterial vaccine type are the substances termed "*detoxicated*" vaccines. It is thought that, with

the endotoxin removed, it may be possible to use much larger doses of the vaccine, and thus obtain proportionately large responses in the way of cell-destroying antibody. If a means has been devised of removing the endotoxin, without at the same time altering the nature of the bacterial cell-substance, which is then left for purposes of inoculation, the antigen produced may be of service. These detoxicated vaccines are on trial, but as yet we cannot judge of their value. It remains to be seen (1) whether it has been possible to effect the segregation attempted, and (2) whether, after all, the endotoxin may not really be an essential ingredient of a specific bacterial vaccine designed to stimulate active immunity; in which case, although it would of course be possible to give much larger doses of the "detoxicated" material without producing undesirable reactions, the practitioner would risk being constantly subminimal in his dosage of the vaccine.

THE CHOICE OF THE REMEDY

It is not always easy to decide as between the use of an appropriate serum or an appropriate vaccine—assuming both of these have proved virtues—in any given case of infection. In acute cases it is a sound practice to begin by the use of a serum and follow this by the use of an autogenous vaccine if obtainable. It should be remembered that sera and vaccines act in quite different ways. Sera act quickly, but their action is soon over. Vaccines act slowly, but their action lasts longer. Sera call for no active response on the part of the patient's tissues. Vaccines stimulate the patient's tissues to the production of specific substances. It is difficult to lay down any general rules, but it may be said, *ceteris paribus*, that if the infection is acute (and) or generalised, and if the patient is very ill, the use of a serum is likely to prove efficacious; whereas if the infection is chronic (and) or local, and the patient is not very ill, the use of a vaccine is likely to be of service.

THE MODE OF ADMINISTRATION OF IMMUNE SERA

(a) *By subcutaneous injection.*—This is the method in common use. The best place for reception of the serum is the loose cellular tissue of the flank or lower abdomen. After cleansing the skin by soap and water followed by absolute alcohol or acetone, or after painting it with a little iodine in spirit, the serum is injected very slowly, avoiding as far as possible any jerky movements of the piston. The syringe and needle have been previously boiled, and the phial containing the serum has been warmed to body-heat. In making the injection it is important to make sure that the needle has really entered the subcutaneous tissues and is not still in the deep layer of the skin, which may easily happen if the common practice of pinching up a narrow fold of skin for the purpose of the puncture is followed. It is much better to keep the skin well stretched by means of finger and thumb and to insert the needle boldly into the stretched surface. The patient will be grateful for the choice of a fine rather than a coarse needle,

and one which is either new or freed from all traces of rust before use. In the event of 50 c.c. of serum being given, half of this quantity should be injected on either side.

(b) *By intravenous injection.*—This method deserves wider use, especially in cases of very acute and serious infection, and in others in which the use of antiserum has been delayed. The method involves no risk, although it needs care and scrupulous asepsis. The serum is generally diluted before use, with two or three times its bulk of normal saline. In many severe cases intravenous saline solution is itself of service, and when this is thought to be so, the serum may be added to the saline infusion.

The injection is best made into a prominent vein at the ante-cubital fossa, the skin being treated as described in (a). When the syringe has been filled with the warm serum, the arm is constricted by a single round of bandage well above the elbow, or an assistant constricts the arm by firm pressure of the hand, so as to render the veins prominent. The patient's arm is fully extended and his hand is tightly clenched. When blood is seen oozing into the barrel of the syringe, the operator knows his needle has entered the vein; the bandage or pressure can now be relaxed and he can now slowly inject the contents of the syringe. If blood does not appear, the needle is withdrawn slightly lest its point may have re-entered the wall of the vein on the opposite side. The serum must not be injected unless it is certain that the point of the needle is in the lumen of the vein. The injection being completed, the needle is quickly withdrawn, the skin being supported by the operator's finger. The patient's arm is then raised at right angles to the body.

(c) *Per rectum.*—This method is sometimes used because it is assumed that the subcutaneous route is painful and distressing, or because the resulting serum reaction is not so marked. But neither of these considerations is of such importance as to determine this route if an immune serum is really indicated. If this route should be decided upon, however, the dose of the serum should be diluted with normal saline solution to make the total bulk not less than 100 c.c. The rectum should be cleaned by an ordinary enema of water, prior to the injection of the diluted serum.

(d) *Per os.*—There is still less to be said in favour of this route, despite the fact that it has been proved that certain antitoxic sera (e.g. diphtheria antitoxin) are capable of exerting their specific effects when given by the mouth. The objections to the method are obvious. If, however, this route is chosen, the serum should be diluted to at least 50 c.c. in bulk, and should be given as far as possible when the stomach is empty.

(e) *By intrathecal injection.*—In cerebro-spinal fever, in other cases of meningitic infection and in some cases of tetanus, this is the best route by which to administer serum. Lumbar puncture is first performed in the ordinary manner and an amount of cerebro-spinal fluid at least equal to the amount of serum to be injected is allowed to run off. The serum is then allowed to flow into the lumbar cisterna by gravity from a height of about 9 to 12 inches, or it is injected very slowly by means of an all-glass syringe. If due care be taken to inject very slowly, there appears to be no objection to the former method, despite the claims made for the latter by certain American observers. In either case the serum should be warmed to body-

heat before it is injected. The patient is placed with a slight inclination of the shoulders downwards during the injection, and this inclination may be increased somewhat afterwards, and kept so for an hour or more. In most cases the injection, as the preliminary lumbar puncture, is best done with the patient under general anæsthesia.

SERUM SICKNESS AND ANAPHYLAXIS

(a) *Serum sickness*.—The use of horse serum, whether normal or immunised, and especially when given by the subcutaneous route, often leads to certain symptoms of a non-specific character ~~on or~~ about the eighth day after the first dose has been administered. These symptoms consist of an urticarial rash, with pruritus which may be very troublesome, mild pyrexia, pain in and swelling of the joints, and some malaise. The urticaria may be concentrated about the site of injection of the serum, or it may be generalised. There may be local or general oedema, but the latter is uncommon; so, too, are albuminuria and swelling of the lymph glands. In some cases the local urticaria appears much earlier than the eighth day; it may appear within a few hours of the initial puncture, the more general symptoms showing themselves towards the end of the week. "Serum sickness" is rarely serious. Treatment is by anti-pruritic lotions, such as saturated bicarbonate of soda solution, or dilute carbolic acid (1 : 100), and by aspirin internally. Some observers consider lactate of calcium of service, but the authors' experience of the drug in this condition does not confirm this view of its helpfulness. It may be added that if the joint symptoms precede the rash—a rare event—some difficulty may arise in diagnosis.

(b) *Anaphylaxis* (see p. 23).

THE MODE OF ADMINISTRATION OF VACCINES

(a) *By subcutaneous injection*.—This is the method of administration in common use; the site usually chosen is the outer aspect of the arm, about one-third of the distance down from the shoulder to the elbow. But when the patient is in bed, the flank or buttock or infraclavicular region is even better, because the subcutaneous tissues are looser in these regions. It is considered by some authorities that in the case of local lesions, some advantage is to be gained by injecting the vaccine near by, but as to this there are no data of a confirmatory kind available. Before inserting a dose of vaccine the skin is prepared as already described (see p. 28). The same precautions are observed in regard to the syringe and needle. No dressing is required to cover the minute puncture.

(b) *By intravenous injection*.—This method has often been employed recently, and its value is still a matter of much debate. It is complicated by the fact that it is liable to lead to the condition termed protein shock, a state of affairs somewhat alarming, induced by the introduction of foreign protein matter into the blood stream. *Protein shock* is in itself capable of exercising a curative action in certain disease-processes, and it may be employed for this reason quite apart from vaccines used for their true

specific effects. It remains to be seen, after much more work has been done in this sphere, how much of the benefit at present ascribed to vaccine therapy is really due to this peculiar reaction.

(c) *Per os*.—The oral use of vaccine therapy is open to the same inherent objections as the oral use of serum. But in little children and in patients who cannot overcome their natural antipathy to inoculations, it may be permissible to employ it. As in the case of sera, the vaccine must be brought up to a certain minimum bulk and must be administered when the stomach is empty (see p. 29).

THE IMMEDIATE EFFECTS OF VACCINE ADMINISTRATION

There are three kinds of reaction possible after vaccine administration—*local*, *general*, and *focal*. (a) *Local reaction*.—It is only after the use of prophylactic doses of vaccine that a local reaction is likely to appear, *i.e.* when the dose chosen is considerable, as in the preventive treatment of typhoid fever. In curative inoculation it is doubtful if local reactions are of any value in order to get results.

(b) *General reaction*.—Here, again, the prophylactic use of vaccines is usually accompanied by this form of reaction, whereas in their curative use, little or no such disturbance is aimed at. After a prophylactic inoculation the temperature may rise to 101° or 102°, and there may be considerable malaise. There may even be a slight rigor. The symptoms subside after 12 hours, and they are usually milder if a second prophylactic dose be given a few days later.

In curative inoculation, provided the scheme of dosage be carefully chosen, general reactions of this character do not occur. After the initial dose there may be slight headache and lassitude, with a rise of temperature to 99° or 99°·5 F., but quite often, if the patient be not apprehensive and therefore anticipating malaise, no disturbance of the general health occurs at all. In acute and generalised infections such small doses of vaccine are usually chosen that no constitutional disturbance results. The degree of the general reaction is probably proportionate to the size of the dose and to the virulence of the bacterial endotoxin. Unfortunately there is at present no standard of virulence of the bacterial endotoxins. Different strains of the same micro-organism differ much in virulence, and a virulent strain is apt to lose its potency, it may be very quickly, on subculture.

For these reasons it is very difficult to anticipate the degree of reaction which a vaccine of known strength as regards the content of bacteria it contains will produce. The principle guiding most workers in practice seems to be that in cases of chronic and local infection a mild but definite reaction is aimed at, but in cases of acute and of general infection no reaction is sought. This mild reaction need not, of course, be produced by the first dose of vaccine; indeed, it is probably better to lead up to it by the use of preliminary doses that do not lead to reaction.

(c) *Focal reaction*.—Neither the local nor the general reaction can be said

to be specific in nature. Sometimes, however, a focal reaction occurs—that is, an exacerbation of the inflammatory interaction going on at the seat of the lesion, if such be present. Such a reaction is probably specific, and for this reason deserves very careful observation. There is a growing belief that such focal reactions should not be aimed at, though they are not necessarily prejudicial if they are mild in their degree.

THE PROPHYLACTIC USE OF VACCINES

A good deal of useful exploitation of the principle of preventive inoculation has recently been undertaken. The most promising results have been those obtained in typhoid and paratyphoid fevers. In plague and in cholera the results, though on the whole favourable, have not been so uniformly good. During the recent epidemics of influenza, a good opportunity has been afforded of testing preventive inoculation: the results will be considered later (see Sect. B, under Influenza).

Experiments, by one of the present writers, have demonstrated the fact that rabbits are rendered less susceptible to infection by pyogenic cocci if they are previously inoculated by vaccines derived from these micro-organisms. This fact, and some general experience, makes it probable that patients who are about to be operated upon, and who are the subjects of sub-infection by cocci, especially when the sub-infection involves the area of operation, have something to gain by similar preventive inoculation. Instances of such operations are the removal of the tongue, prostatectomy, and certain operations upon the throat and the gastrointestinal tract. It is difficult to understand why this field of therapeutics is at present so little cultivated.

It is possible that preventive inoculation of contacts in an epidemic of cerebro-spinal fever may prove to be of service seeing that rabbits have been proved to acquire considerable immunity against the meningococcus after inoculation by the killed coccus (Horder and Gordon).

CASES SUITABLE FOR VACCINE TREATMENT

Provided that the employment of a vaccine is not allowed to interfere with any other recognised and helpful method of treatment, and provided the dosage employed be carefully chosen, the actual field of trial may be made very extensive. This may be said without subscribing to the commonly expressed opinion concerning a case in which the use of a vaccine is being discussed, that “if it does no good, at least it does no harm.” For it is scarcely credible that any remedy which possesses potentialities for great good is not also possessed of power for harm when misapplied. Two subsidiary points often require consideration in connection with the decision to use vaccines in the treatment of an infective process. the assistance of a thoroughly trained and competent bacteriologist and the supervision of the treatment by an observant practitioner.

No hard and fast rules can be laid down as to which cases are, and which cases are not, suitable for treatment by inoculation. Some authorities will

advise that every case of infection be so treated ; others will doubt if the method is indicated with an almost equally sweeping embargo. No doubt wisdom lies, as usual, somewhere between these two extremes. The reader must be warned against confusing certain hypotheses of a purely theoretical kind as to the operation of vaccines with the ascertained facts of clinical medicine. On the other hand, he must also be warned that conclusions based upon prejudice against the method, either from ignorance or from lack of personal acquaintance with it, are equally fallacious. It will be assumed that he is aware of the element of commercialism that has not been slow to creep into the whole subject of specific therapy and threaten to disturb the true indications for its use.

AUTOGENOUS AND STOCK VACCINES

Whenever it is possible to prepare an autogenous vaccine within reasonable time, this should be done, and the use of any other kind of vaccine should be regarded as *faute de mieux*. If the nature of the infection is definitely established it may be advisable to employ a vaccine of a kind known to correspond with the infection, but made from another source, pending the arrival of the autogenous vaccine. Such vaccines prepared in readiness for use in well-established infections are, for convenience, termed "stock" vaccines. With the growing popularity of vaccine therapy the use of stock vaccines has increased enormously, and it is probable that this fact has led to a good deal of the disrepute into which this system of treatment has fallen in some quarters. There are certain circumstances in which the use of stock vaccines is not only justified but obligatory. (1) In most instances where the vaccine is used for prophylactic purposes. (2) In cases where the nature of the infection is certain, but in which the infecting micro-organism cannot be isolated, as in some cases of gonococcal arthritis or of erysipelas. (3) In cases of infection in which the causative microbe grows on artificial media with great slowness, as in tuberculosis, streptothrix infections and simple acne. (Recent methods of facilitating the growth of these micro-organisms render the use of autogenous vaccine less difficult than formerly.) (4) It is good practice to use a stock vaccine of a more virulent strain of micro-organism or of several different strains, if it is found that little or no good follows the use of an autogenous vaccine. (5) The expense of making an autogenous vaccine may be prohibitive.

DOSAGE OF VACCINES

For the choice of dose and for the frequency of vaccine administration, reliance must be placed at present upon a careful study of the clinical condition of the patient and upon a large experience of similar cases already treated by this method. In the concrete suggestions made in the following sections with regard to dosage in the various infections, it is experience that will be taken as the chief guide in the matter, fallacious as this guide is notoriously known to be.

There are several reasons for regarding the opsonic index, though it

may be of value in diagnosis, as an inadequate measure of the degree of total immunity of a patient to the infecting microbe. These reasons cannot well be gone into here. And in any case, whether it is that this opinion is now shared by clinical pathologists generally, whether the hypothesis upon which the opsonic index rested is now regarded as improbable, or whether, as is more likely, a determination of the opsonic index has been found to be unnecessary for the purpose of actual practice, it is certain that, as a technical guide to dosage in vaccine therapy, this system of notation is no longer practised.

Experience has shown that the effective range of dosage, at least as regards the pyogenic cocci, is fairly wide; within this range, though the expert will probably cure more quickly and more pleasantly than will the amateur, by his more judicious choice of dose and time-interval, no bad effect is likely to follow in chronic diseases. In acute and in generalised infections no doubt the range of safety is much less; this only means, however, that in any case of doubt the smaller of two proposed doses should be chosen, at least for the beginning of the treatment.

This experience confirms the results of animal experiments, which prove that, in the case of staphylococcal vaccine, the immunity conferred upon rabbits will be independent of doses varying as much as 100 per cent., and this without any demonstrable ill effect (Horder).

Brief reference should perhaps be made to the variation in the strength of antigen in different preparations of the same vaccine. This seems inevitable in the present state of our knowledge. Different cultures possess different degrees of virulence, according to the nature of the strain of the micro-organism, the particular culture media, etc. These remarks apply in particular to the gonococcus, the pneumococcus, and various strains of streptococci. This fact detracts much from the value of suggested sizes of dose of those and some other vaccines.

There is more agreement, or rather more conformity in practice, in regard to the time-intervals between the inoculations, than there is in regard to the size of the initial dose and the rate of increment. Speaking quite generally, a time-interval of a week to 10 days is the rule of practice in cases of chronic or of subacute infection, and of 48 to 72 hours in acute infections. The increment in the dose is chosen arbitrarily, but the immunisation is guided by the size of the initial dose, by the degree of reaction (if any), by the nature of the infecting agent, and by the clinical condition of the patient. In regard to these two factors (increment of dose and time-interval between the doses) different observers employ different systems. Thus, the successive doses may show the same definite percentage increase throughout the series: 5, 7½, 10, 15, 20, etc. million, or 5, 10, 20, 40, 80, etc. million, or they may be given in pairs of the same size: 5, 5, 10, 10, 20, 20, etc. million. In both cases the same time-interval, would be maintained throughout. The advantage of the latter method, a favourite one with the writers, is that undesirable reactions are more likely to be avoided, and a good comparison is given between the effects of the same individual dose upon the patient's condition at different stages of his disease. Still a third system is sometimes followed: a series of three doses is given at short and regular intervals, with a definite increment (say 100 per cent.) between the doses, a larger interval is then allowed to elapse and a second series of doses is given, the first dose of which is

the same size as the second dose of the first series, and so on. The third system is useful in acute infections, and when large doses of a sensitised vaccine are being used.

The factor of *sex* does not introduce much variation in response to vaccines, but the writers' experience suggests the advisability of choosing somewhat smaller doses in females. *Age* introduces a very definite variation: in children under 6 years the adult dose should be divided by four, and in children between 6 and 12 it should be halved. From 12 to 16 two-thirds of the adult dose should be given.

When there is any considerable difference of practice, the writers have taken the mean position; for where both extremists claim excellent results, and are temperate observers, there should be wisdom in striking an average. The doses are stated tentatively, because they are by no means arbitrary, and they are to be modified in individual cases as seems necessary. Custom is a potent influence in this matter, as in medicine generally, and, though the method of inoculation has long since passed the stage of experiment in its main principles, rules of practice are frequently changing.

SOME GENERAL RULES IN THE USE OF VACCINES

1. Use every effort to establish an accurate diagnosis, not only in regard to the nature of the infecting micro-organism or micro-organisms, but also in regard to the duration, course and degree of the disease-process.

2. Use only pure cultures in the preparation of the vaccine.

3. Use autogenous vaccines whenever possible.

4. In the case of mixed infections, endeavour to get some close approximation to the actual condition in regard to the chief, as against the secondary, infecting agents.

5. Avoid the use of vaccines that have been subjected to much heat in their preparation, and vaccines that have been kept for a longer period than 6 months.

6. In the treatment of a prolonged case, reconsider the bacteriological diagnosis now and again. There are two reasons for this: the flora may have changed in the meanwhile, thus necessitating the use of an entirely different vaccine; and there are some reasons for thinking that a micro-organism gets "acclimatised" to its corresponding vaccine.

7. Begin by small doses until the patient's response is ascertained; no harm is done if the initial dose is subminimal in its size. It is easy to waste time, but it is difficult to save it, by overdoses.

8. Do not "flog" the patient's immunity mechanism by too rapid repetition of the inoculations.

9. Do not get into a panic, and mistake undue hurry in the preparation and administration of a vaccine in the case of acute infections, for promptness in treatment. Panic may be excusable in the patient's friends, but it is unforgivable in the doctor.

10. On the other hand, do not conclude that a vaccine is useless because a miracle does not follow its initial application. If you decide to try it, the reasons guiding you should be such as to justify a thorough, and not a casual, trial of the remedy. Especially is this important in very chronic

cases in which results may not be apparent until the inoculations have been steadily continued over a lengthy period.

11. If in doubt as to whether a dose of vaccine should be given or deferred, defer it. Intercurrent illness, a long journey, a menstrual period, the anticipation of a fatiguing or exciting time immediately after the inoculation—any of these should lead to postponement of the injection.

12. Relax no single adjunct in the general treatment of the patient because vaccines are being employed. Remember that the immune process is extremely complex in its operation, and therefore that it is open to assistance in many different ways, of which the most important, no doubt, is some form of immune therapy. But non-specific measures are also of importance, especially in the fight against those diseases concerning which, as yet, the measures for increasing specific resistance are in an experimental stage.

13. Know what it is you are trying to do, and, so far as is possible, understand the nature of the material with which you are trying to do it. Control your remedy, do not let it control you.

(B) PARTICULAR

We shall now deal in concrete with the various infectious diseases and infective processes for which there are available remedies in respect of immune therapy. For convenience of reference an alphabetical arrangement will be followed. Stress will be laid upon those infections that are commonly met with in Great Britain.

ANTHRAX

The best treatment probably consists in simple excision of the pustule and the early use of an immune serum. The extensive surgical procedures that were once in common use are not now in favour. There are two sera in present use, *Sclavo's*, to be obtained in England from Messrs. Allen & Hanburys, and *Mulford's*. A liberal dose should be injected subcutaneously, not less than 50 cc., which may be repeated. In very acute cases, and especially if the treatment has been deferred, the initial dose should be given intravenously, following the general rule of practice. Anti-anthrax serum is believed to be "bactericidal" in its action.

CATARRHS, CHRONIC AND RECURRING

Treatment, both prophylactic and curative, by means of vaccines, may be adopted for the various forms of recurring sore throat, the common cold, chronic naso-pharyngitis, and chronic or recurring tracheitis and bronchitis. The micro-organisms most often isolated are pneumococci, *M. catarrhalis*, streptococci, and Pfeiffer's bacillus. It is not possible to generalise as to dosage and time intervals where so many varying ætiological factors are concerned. But the results of vaccine treatment in this group, though

by no means uniformly good, are sufficiently encouraging to justify thorough trial, especially when other methods (non-specific) fail to relieve the patient.

CEREBRO-SPINAL FEVER (AND MENINGOCOCCUS INFECTION GENERALLY)

Much work has been done in recent years in connection with anti-meningococcus sera. At first the results were disappointing; then a serum prepared by Flexner against the strain of meningococcus present in the New York epidemic appeared to have good results; then this serum, and others, seemed to fail conspicuously in a large number of the cases occurring in Great Britain in 1914-1916. The experience of the epidemic in this country led Gordon to group the meningococci responsible for the cases; and for Gordon's four types of the coccus, corresponding sera have been manufactured and are on trial. In the case of anti-meningococcus serum, *which must be given intrathecally*, it is difficult to say how much of any benefit that follows its injection is due to the action of the serum and how much is due to the attendant drainage effected by the lumbar puncture. The usual dose of serum is from 20 to 50 cc., according to the severity of the case, and according also to the amount of cerebro-spinal fluid allowed to drain off at the time of the puncture. (Rather less serum must be run into the theca than the amount withdrawn.) The technique is referred to in the article on Cerebro-spinal Fever. The serum is repeated from time to time according to the progress of the case. If good results are not obtained, it is wise to change the serum for another brand.

Meningococcus septicæmia is treated by a full dose of the serum given intravenously—not injecting less than 50 c.c.

Meningococcus arthritis is treated by serum subcutaneously, and may also be treated by injections of the serum into the affected joints.

COLIFORM INFECTIONS¹ (“*B. coli*” INFECTIONS)

Anti-colon bacillus sera have given but little evidence of value as therapeutic agents. Coliform vaccines are, however, of definite service in a large number of these infections. In the experience of many, their efficacy ranks next to that of staphylococcus vaccine.

The great number of different coliform infections that are met with makes it imperative to deal with autogenous vaccine if any degree of success is to be expected.

1. *Infections of the urinary tract.*—Opinion varies much as regards the results of vaccine therapy in these cases. The diversity of experience may find an explanation in the fact that the cases are of such divers sorts. (See p. 79, *Bacillus coli* Infections.) There seems no doubt, however, that the method is a very useful adjunct to general and local measures in certain cases, constitutional symptoms being relieved, dysuria reduced, and pus in the urine much lessened in amount. In true *Bacilluria* the same good results must not be expected as in states of infection.

The most common system of dosage is to begin with 5 million bacilli,

¹ I.e. infections by bacilli of the coliform group.

in order to test the patient's tolerance, increase to 10 million a week later, and gradually increase farther up to 100 or 250 million, maintaining the time-interval at 7 to 10 days throughout. Whenever the treatment is carried out over a lengthy period it is important to secure a fresh culture from the urine from time to time for the purpose of making a new vaccine.

Prophylactic treatment by coliform vaccine may be advisedly resorted to before the operation of prostatectomy, should this procedure be decided upon in the presence of an infected urine.

2. *Post-operative suppuration* is frequently due to coliform infection, with or without infection by the pyogenic cocci: a common instance is appendix operation during or after abscess formation. The question of inoculation should arise in any such case if convalescence, or healing, be delayed. Some gall-bladder operations call for the same comment.

The dose of vaccine, whether "pure" or "mixed," should be small, at least at first—5 to 10 million coliform bacilli, the same number of streptococci (assuming the infection to be by *S. faecalis*), and 50 to 100 million staphylococci. The frequency of dose, and its subsequent increase, are determined by the clinical features of the particular patient.

3. In "*colitis*," careful consideration must be given to the question of an exact diagnosis, if at all possible. Thus, it must never be assumed, as it not seldom is, that any unselected case of colon infection is of necessity coliform: the contrary is quite frequently the fact: cases of ulcerating colitis are quite often associated more nearly with streptococcal than with coliform infection. Then, again, considerable care should be shown in the choice of the colonies from the culture plates obtained by the examination of the faeces, so as to work with any coliform strain which may be found to be atypical.

For this reason the help of a skilled bacteriologist is quite essential. To use "stock" vaccines is to invite failure. As may be expected, the results will turn very largely upon the degree to which the infective element is dominant ætiologically. In the muco-membranous type of case (*C. nervosa*) treatment by vaccine is not likely to avail much. The dosage of vaccine may well follow the rough indications set out above.

A very important type of case is that in which there is evidence that both urinary and intestinal tracts are infected; these cases amply repay the practitioner for careful study in conjunction with an expert bacteriologist.

DIPHTHERIA

This infection is treated wholly by serum; specific inoculation is not indicated, so successful is the serum treatment. The serum is an antitoxin serum. For success in its use two considerations are necessary: it must be given early in the disease, and it must be given in sufficiently large doses. It has been shown by careful observers that the mortality from the disease rises steadily day by day during the first week of the disease with each day's delay in the use of the serum. Delay in diagnosis, or in use of the serum, can be to some extent, but not altogether, made up by administering a larger dose than would otherwise be necessary.

In a mild case, and if the serum be given early, not later than the second day of the disease, 5000 units will probably suffice. If treatment begins only on the fourth day, 10,000 units should be given, in two successive doses at an interval of 12 hours. *If the case is a severe one*, or if there are laryngeal symptoms, these doses must be increased, respectively, to 10,000 and 20,000 units *for the initial dose*, and these doses must be repeated once or twice during the course of the disease if this is unfavourable.

Neither *age* nor *sex* should affect the size of dose of antitoxin. In any case which is clinically doubtful, the serum should be given before awaiting the bacteriologist's report. It should be remembered that a stained film of the exudate may give considerable presumptive evidence of diphtheria before a report can be obtained on the cultures.

The antitoxin is usually given by the subcutaneous route (see p. 28). A dose may well be given intravenously if the serum be administered late or if the case be very severe.

The type of the disease is quite immaterial to the success of the remedy; all varieties of infection by the Klebs-Loeffler bacillus—even skin infections—indicate the use of the serum.

Diphtheria antitoxin is of service as a prophylactic, in doses of 1000 or 2000 units. The protection thus conferred does not, however, last many weeks. Some workers prefer inoculation by one or two doses of 50 million diphtheria bacilli as a method of achieving prophylaxis.

For serum rashes and other immediate effects, see p. 30.

For immunisation by the Schick method, see p. 101.

GNOCOCCUS INFECTIONS

At the present time there is no gonococcus serum possessing sufficient potency to justify its use; immune therapy in this infection is achieved entirely by gonococcus vaccine.

Reference has already been made to the varying virulence of different strains of gonococci. Whenever possible, therefore, it is important to employ the actual strain of gonococcus causing the infection in preparing the vaccine. It is also very important to prepare the vaccine from the first subculture at latest, so quickly does this micro-organism lose its virulence on artificial media. But in a large number of cases of gonococcus infection an autogenous vaccine is out of the question, and it is necessary to fall back upon "stock" preparations. A stock gonococcus vaccine should be made from recent cultures of several strains of gonococci. Such a vaccine can usually be obtained from pathological institutes on whose staff is a skilled bacteriologist interested in vaccine therapy.

Acute urethritis, acute vaginitis and cervicitis.—If it be decided to help the local treatment in those diseases by the use of vaccines, small doses (1 to 5 million) are given every 3 to 5 days. But such treatment is not usually given, reliance being placed entirely upon local measures.

Chronic urethritis, vaginitis, cervicitis; gleet.—Here, again, local measures form the customary rule of practice. But vaccines are of more service here than in the last-named group of diseases. Ten to fifty million cocci may be

given every 5 to 10 days. Due attention must, of course, be paid to mixed infections (e.g. by staphylococci).

Gonococcus arthritis (gonorrhæal rheumatism).—Following a general rule, that vaccines are of greater service in those infections in which there are constitutional symptoms than in those in which the whole manifestations are local, it is found that vaccines are of more help in this condition than in either of those formerly mentioned. If the case be acute, the dose should be small—1 to 5 million cocci given at intervals of 3 to 5 days. If the case be subacute, doses of 5 to 10 million cocci may be used, at about the same intervals. In chronic cases 10 to 20 million cocci form an appropriate initial dose, and this may often be increased with advantage: 50, 100, and 250 million cocci at weekly intervals. Good results sometimes follow doses of 400 or 500 cocci, when the fibrositis is of some duration and is very chronic. Some workers have used doses as large as 1000 million, and have reported good effects; but it is probable that they have been using stock vaccine prepared from cocci whose virulence is very low. In some instances living cocci have been injected intravenously (Broughton-Alcock).

Acute iritis.—This condition calls for considerable caution if vaccines be employed: 0.5 to 1 million should be tried tentatively. It may even be wise to allow the acute attack to subside before giving any vaccine at all, and then to treat by small and graduated doses so as to check the relapses of this condition which are so prominent a feature of the disease.

INFLUENZA

At the time of writing this article the whole subject of the pathogenesis of influenza is under discussion. The simple view that influenza is a specific entity, and that it is essentially due to infection by Pfeiffer's bacillus, can scarcely be maintained in the light of the great body of experience afforded by the pandemic of 1918-19. It seems probable that the initial causative agent is at present unknown, or certainly unisolated (but see article on Influenza, p. 123), and that the flora hitherto dealt with, even in the cases of the disease succumbing rapidly, do but cover the secondary invaders of tissues that have become highly predisposed to infection. These secondary infections are *B. Pfeiffer*, the pneumococcus, streptococci and *M. catarrhalis* chiefly, though other micro-organisms, such as staphylococci, must be added to the group.

It seems certain that uncomplicated cases of the disease are either very mild or very severe, and that intermediate cases are so much the subjects of secondary infection that this fact must be taken into account in any consideration of specific therapy. If this view be correct, it does not follow that vaccines at present obtainable may not affect the primary incidence of the disease; because it is possible that the primary infection may not occur, or may abort early, if the resistance to these secondary infections has been raised. Such a possibility gains credence from the known fact that certain micro-organisms may multiply much more rapidly, or may not multiply at all, in close association with other micro-

organisms (Symbiosis). Whether this affects the present question or not, it remains true that so many of the serious, not to say lethal, processes taking place in the course of the disease are intimately connected with (? are due to) the secondary infections, that it is highly desirable to employ vaccines in both the prophylactic and the curative treatment of the disease.

For the prophylactic treatment the "War Office formula" advises two doses of vaccine, to be given with an interval of 10 days. The composition of the first dose is: *B. Pfeiffer*, 30 million; pneumococci, 100 million; streptococci, 40 million. The second dose is to be exactly double the size of the first. Matthews and Horder both comment on the small proportion of the *B. Pfeiffer* constituent in this formula, and urge that this should be much larger, such as 100 to 200 million for the first dose, and double this amount for the second dose. These increased figures assume that the bacillus is grown upon Matthews' trypsinized blood medium. Emery criticises the formula in that it contains no *M. catarrhalis*, which, as he points out, certainly occurs in vast numbers in the lungs of some of the fatal cases, and is undoubtedly a secondary infection of considerable importance. W. H. Wynn suggests that the content of pneumococci is too small. In face of these conflicting views it is not surprising to find a large number of different formulæ available, and the practitioner is not a little bewildered in consequence.

For curative treatment in influenza the present position is even more lacking in uniformity of practice than it is in regard to prophylaxis. The writers cannot do better than quote Emery's summary of these conflicting opinions (*Practitioner*, February 1919). "In severe cases of broncho-pneumonia they (*i.e.* the War Office committee) express the opinion that the use of the prophylactic vaccine cannot be recommended in view of the dangerous rapidity and severity of these cases, but when it is tried they suggest that the initial dose should not exceed one-twentieth of the first dose described above, *i.e.*, 1½ million *B. influenza*, 5 million pneumococci, and 2 million streptococci. Many bacteriologists hold that it is especially in these acute cases of broncho-pneumonia that the use of vaccines is most strongly indicated, always assuming that the treatment can be begun early. Thus Wynn urges the immediate treatment of influenza by giving adequate doses within a few hours of the onset; the dose that he suggests is 50 million pneumococci, 50 million streptococci, and 30 million *B. influenza*—how cultivated is not stated. This probably represents the best we can do for the patients, and there seems to be sufficient evidence available to justify us in the belief that patients who have had a dose of vaccine at the very beginning of the attack usually escape without severe symptoms." With this summary of Emery's, the writers agree in the main. The cases differ so notoriously in the particular course they run, and the flora is so extraordinarily variable, that the writers prefer not to continue with the formula above set out, but rather to vary it according to the investigation made in individual cases. Nor does this often require the labour and the time spent in cultural examinations: a rapid survey of films made from the sputa will again and again give very valuable indications for a formula adapted to the particular case. Emery notes the importance of this point also.

PNEUMOCOCCUS INFECTIONS

Up to the present time the results of the use of anti-pneumococcus serum have been even more disappointing than has been the case with anti-streptococcus serum. But an attempt has been made to "group" the pathogenic pneumococci, and corresponding group sera have been prepared (Rufus Cole) which may give better results. Vaccines are a more popular remedy at the moment, either used as "naked" vaccines, or as sensitised vaccines.

1. *Pneumonia*.—Opinions differ, or practice differs, in regard to the utility of vaccines in the treatment of pneumonia. There is general agreement that if inoculation is to be employed, it should be during the early stage of the disease, before massive consolidation has occurred. If this stage has been reached, it is better to defer inoculation treatment until such period as "delayed resolution" occurs, or the non-advent of a crisis by the tenth day.

The vaccine used should be autogenous if practicable, the pneumococcus being obtained either from the sputa or by lung puncture. But as it is obvious that inoculation during the first 48 hours of the disease cannot be done by the use of autogenous vaccine, the immunisation must be effected at this period by the use of "stock" vaccine. A dose of 5 million cocci may be given as early as the disease is diagnosed, 10 million on the next day, and 25 million on the day following. Some observers give an initial dose of 50 million cocci, and do no more. At the later stage (crisis delayed) the doses should be of the same size.

2. *Broncho-pneumonia*.—The results of vaccine treatment are better here than in lobar pneumonia, probably because recrudescences and relapses are much more common, and may be prevented by this treatment. The patient is generally a child, and the doses should be 2, 3, 4 and 5 million, with intervals of 3 or 4 days.

3. *Empyema*.—Drainage being satisfactorily established, the closing of the sinus may be assisted by the use of 10 to 50 million pneumococci in weekly doses.

4. *Bronchitis; asthma; infections of the upper air passages*.—In this series of diseases, vaccines are often very useful adjuncts to measures of a more general kind. Success turns largely upon the degree to which the infection is "pure" and not "mixed." The course of the disease process is usually chronic, and for this reason larger doses of vaccine may be given (e.g. 10 to 500 million at weekly intervals), and should be maintained over a long period of time. (See also Catarrhal Infections.)

5. *Pneumococcus septicæmia and pyæmia*.—The principles and details of treatment are the same as in generalised streptococcus infections (see p. 44).

STAPHYLOCOCCUS INFECTIONS

The immune treatment of staphylococcus infections is entirely by vaccine. This is due to two reasons. Vaccines have been more successful in these infections than in any others; and no staphylococcus serum of any potency in bactericidal substances has as yet been produced.

1. *Chronic local infections*.—These consist of boils, carbuncles, pustular

acne, onychia, sycosis, otitis media (sometimes), eczema (sometimes), ciliary blepharitis, suppurating Meibomian cyst and certain discharging sinuses. Furunculosis and certain other staphylococcal infections were the first to be treated systematically by Wright's method of specific inoculation, and, as a class, these infections yield, with care, almost uniformly good results. It may certainly be said that it is uncommon to get an instance of complete failure to respond to vaccine treatment.

A guarded prognosis must, however, be given in connection with each of the other forms of staphylococcus infection. And in all the cases care must be exercised to see that the general points in treatment are receiving attention. If these be omitted, failures will frequently be met with in those cases in which the infective factor is not very dominant. In acne, for example, it is unlikely that vaccines alone will effect a cure if local measures be omitted. Here, as always, the inoculations must be regarded as adjuncts to the general programme of treatment, not as a substitute for it.

In the case of suppurating wounds or sinuses, vaccine treatment should never be expected to take the place of efficient drainage, which must in all cases be secured in the first instance.

In the matter of *dosage* there is still considerable difference of opinion and of practice. And yet the results are, as already stated, very good upon the whole: an illustration of the fact, mentioned in the general section of this article, that there is a considerable range of effective dosage with most vaccines. Some workers still use the comparatively small doses which followed as a sort of reaction to the quite large doses that were originally given, but most agree in using a dose of 1000 million in beginning the treatment of a straightforward case. If improvement follows, this is succeeded by doses of 250 to 300 million with intervals of 8 to 10 days. Relapses are quite common, and require a good deal of careful management. Either the doses are not sufficiently large, or the inoculations are repeated too frequently. Each case must be considered on its merits. In the experience of the writers there is often a tendency to stop the treatment too early. It is often of value to "space" the doses more widely as the treatment proceeds.

In the treatment of acne a similar plan may be followed. Some workers use a mixed vaccine of staphylococcus and the "acne bacillus," and record better results (A. Fleming). In sycosis the response to these doses is only satisfactory if the case is treated early. If it is of some standing, and much induration is present, the vaccine should be tentatively increased to 2000, 5000, and even to 8000 million cocci. The same rule applies to many cases of chronic acne. Once more let it be urged that it is courting disappointment to neglect necessary methods of treatment when dealing with these chronic skin infections.

It has become customary to employ stock vaccines in the treatment of furunculosis and other staphylococcus infections, and, as staphylococci appear to differ little in the matter of strains, the success of this convention justifies the practice. If, however, success is not attending the treatment, an autogenous vaccine should in all cases be obtained. This is perhaps more important if the infection is due to *S. aureus* than if to *S. albus*.

2. *Acute local infections*.—A single dose of vaccine certainly tends to cause an acute boil or carbuncle to abort, but it should be administered early to secure this effect. The dose chosen is usually 1000 million of mixed staphylococci. Care must, of course, be taken to give no dose of this size in the presence of any constitutional symptoms which may indicate a general infection. But a general infection may quite probably be avoided by the above-mentioned prompt treatment. In the case of boils of the external auditory meatus and other very painful situations, the more rapid development and consequent resolution of the lesion following administration of a vaccine are of considerable advantage.

Poisoned fingers and acute abscesses due to staphylococcus infection require much smaller doses. They are best treated by (say) 50 to 100 million cocci, with 3 or 4 days' interval.

3. *Chronic general infections*.—In chronic staphylococcus pyæmia vaccine therapy is disappointing. But trial should be made of 50 to 100 million of an autogenous vaccine every 4 to 7 days, omitting the inoculation just prior to, or just after, any surgical procedure, such as the evacuation of an abscess. If there is no good result these doses may be gradually increased.

4. *Acute general infections; osteomyelitis*.—In this condition, as, indeed, in many other acute staphylococcal infections, prompt surgical treatment must be always undertaken. So soon as this is done, or rather, so soon as the culture has been taken, the micro-organism grown and the vaccine prepared—these things occupying the time during which the patient's auto-inoculation from the surgical procedure is making the introduction of fresh antigen necessary—a dose of 25 to 50 million cocci is given. The same dose is repeated in (say) 2 to 3 days, and is perhaps gradually repeated, the clinical condition being carefully watched meanwhile. A case of this kind in which progress hangs fire will sometimes mend rapidly under vaccine treatment.

STREPTOCOCCUS INFECTIONS

Both immune sera and autogenous vaccines are appropriate in the treatment of streptococcal infections: no fast and hard rule can be given in regard to the choice of serum or vaccines: it is a good general rule of practice to treat acute and (or) generalised infections by serum and to treat chronic and (or) local infections by vaccines. In acute cases the serum can, of course, be followed up by vaccine, and this sequence is to be recommended.

The method of using a sensitised vaccine, immediately upon the serum administration, is held by some to be the best method of procedure, but see p. 26. In a chronic case recourse may be had straightway to vaccines.

If the infection is due to *S. pyogenes* vel *S. hæmolyticus*, which it usually is in very acute infections, a univalent pyogenes serum, such as is made by Messrs. Burroughs Wellcome & Co., offers the best hopes of success (Andrewes and Horder).

If, however, the infecting coccus is of the salivary or faecal type (vel *S. viridans*), a "polyvalent" serum may be chosen. If a sensitised vaccine be used, the homologous serum should be used in making it. The chief kinds of streptococcus infection will now be dealt with in more detail.

1. *Arthritis, fibrositis, and allied conditions*, when traceable to streptococcus infection, are attributable to streptococci of feeble virulence. The dosage of vaccine, with the appropriate time-intervals, calls for detailed consideration and some general comments.

In embarking on the treatment by vaccine therapy of infective arthritis, it has to be realised that such treatment will be brief or long according to the time the lesions have existed. In this connection, moreover, it should be borne in mind that even if the lesions are not of long standing, the toxæmia leading to those lesions may be of much longer standing than at first suspected.

Recent cases of infective arthritis only rarely present themselves for treatment, but there should be an increasing tendency in this direction. Such cases will often show definite improvement after the first dose of vaccine; and if the joints involved are the knees, a definite decrease in swelling may be noted.

If well-marked "rheumatoid" changes are present, treatment may have to be carried on for as much as two years, if not more. It is as well in making plans for such lengthy treatment to prepare the vaccine accordingly. This can, as a rule, be arranged for by making two concentrations of vaccine, one concentration being ten times the strength of the other.

The authors recommend that the vaccine be made in two strengths, the weaker strength of a total concentration of 100 millions of streptococci per cubic centimetre, and the stronger one of a strength of 1000 millions per cubic centimetre.

For instance, if a combination of a salivary and an intestinal streptococcus be decided on, two bottles of vaccine are prepared as follows:

1. 25 c.c. Containing per c.c. $100 \begin{Bmatrix} 50 \\ 50 \end{Bmatrix}$ millions $\begin{Bmatrix} \text{salivary} \\ \text{intestinal} \end{Bmatrix}$ streptococci.
2. 25 c.c. Containing per c.c. $1000 \begin{Bmatrix} 500 \\ 500 \end{Bmatrix}$ millions $\begin{Bmatrix} \text{salivary} \\ \text{intestinal} \end{Bmatrix}$ streptococci.

In the course of treatment a stage is arrived at when 1 c.c. of the former strength is being used. The former bottle is then discarded and an equivalent dose is provided by using 0.1 c.c. of the stronger concentration. This latter bottle usually provides for all possible requirements.

The actual treatment varies in different cases. Roughly speaking, 0.1 c.c. of the weaker concentration (i.e. 5 millions of each variety of streptococcus in the case exemplified) usually constitutes an initial dose, and frequently weekly doses increasing by 0.05 per week may be given until a dose of 0.25 c.c. be achieved. Then such doses as 0.35 and 0.5 c.c. may be appropriate. It may then be advisable to prolong the interval between doses to 10 days, and with

such intervals 0.75 and 1 c.c. may be given. With intervals of a fortnight, further doses of 0.15, 0.2, 0.25 c.c. of the stronger vaccine, and with longer intervals still increasing doses.

The guide to the increase of the dose is solely the reaction or absence of reaction caused by the preceding dose. So long as any reaction—~~increase of pain~~, malaise, etc., lasting more than 12 hours—follows any dose, we consider that dose a maximum one, and repeat it until it fails to cause such reaction.

The result of such treatment in many cases is in the first instance a remission of symptoms of the toxæmia accompanying the arthritis. The symptoms in question are: depression, which may be very marked, loss of application, energy and joy in life, and an increasing inability to carry out the ordinary avocations, apart from the handicap imposed by the actual deformities of the disease.

The dread of increasing disability owing to arthritic deformity is replaced by a conviction of eventual cure, in a large proportion of cases, after comparatively few doses of vaccine, and this despite the fact that not rarely no actual diminution of pain may have occurred. In some cases, indeed, perhaps owing to absorption of fluid from joints, the pain becomes actually increased, and yet the patient acclaims benefit.

It is also to be noted that after a variable number of doses of vaccine various forms of local treatment, which may have been tried formerly with only temporary beneficial results, now tend to produce more permanent results.

2. *Cellulitis and acute abscess formation*.—A similar line of treatment may be adopted as is described for *Erysipelas*.

3. *Erysipelas*.—The infection is by *S. pyogenes*. Begin by giving 50 c.c. of univalent pyogenes serum intravenously (see p. 29), and follow this at once by very small doses of vaccine, preferably autogenous, such as 2 to 5 million cocci, on alternate days, for 4 to 6 doses. The serum may be repeated on two to four occasions at intervals of 24 hours, concurrently with the vaccine.

4. *Pyorrhæa alveolaris*.—The material from which the vaccine is prepared is to be taken from the depths of the pockets in the gum, or, better still, from the apex of an extracted tooth, if this be available, and not from the pus lying about the neck of a tooth, which is always the nidus of secondary infections, erroneously thought to be causative of the condition. The initial dose may well be 5 million cocci, followed at intervals of 7 to 10 days by gradually increasing dose: 10, 25, 50, and 100 million cocci. Even larger doses may be profitably given should no "reactions" occur. This treatment is only to be advised when, after conference with a dentist, it is decided not to extract the affected teeth, or only to sacrifice the worst of them.

5. *Septicæmia and pyæmia; puerperal fever; infective endocarditis*.—The treatment recommended, in so far as a general plan can be laid down, is to administer a large dose of serum, intravenously in very acute cases, subcutaneously in others, and repeat the serum in smaller amount daily, or on alternate days, for 4 to 6 doses, or more. The initial dose in very acute cases should not be less than 100 c.c. As soon as an autogenous vaccine can be procured, a very small dose is given, such as 0.5 million cocci, and this is

gradually increased to 2 to 5 million by inoculation about every third or fourth day. In cases of puerperal fever, however, and in some other instances, such as septicaemia following operations on the bowel, etc., the streptococcus isolated from the uterus or from the blood stream is often *S. faecalis*, and as this type of streptococcus is usually much less virulent than *S. pyogenes*, the practitioner may give larger doses of vaccine, such as 50 million cocci. According to Gordon and others, better results follow the use of sensitised vaccine.

In cases of *infective endocarditis* very little good is to be expected from any mode of immune therapy, whether by sera or by vaccines. Nor can much, if anything, be said for sensitised vaccines in this disease. Some of the cases run a prolonged course, and therefore give opportunity for obtaining a human immune serum for purposes of preparing the sensitised vaccine (Horder). See also *Infective Endocarditis* (p. 832).

TETANUS

Next to diphtheria, tetanus is the infection in which the employment of immune serum yields the most marked degree of immunity. Owing to the great difficulty of diagnosing this infection by bacteriological examination of the local lesion, the constitutional effects of the poison cannot often, therefore, be anticipated. By the time the disease is manifest, much of the toxin is already "fixed" in the central nervous system, and the results of treatment by antitoxin are of necessity often unsatisfactory. A certain number of cases have, however, definitely begun to improve after use of the serum, especially when its administration has been prompt.

The best route by which to give the antitoxin is still a matter of debate. Some authorities advise intrathecal and intracerebral injections of the serum, so as to try to neutralise the toxin in the nerve structures. A reasonable method of treatment is to inject 500 units of antitoxin by lumbar puncture immediately the diagnosis is made and 1000 units subcutaneously. These injections may be repeated daily for 4 to 6 days.

The *prophylactic* use of tetanus antitoxin has proved quite as successful as its use for curative purposes has been disappointing, and there is little doubt that the case-incidence of the disease was much diminished by the employment of "A.T.S." during the Great War, and that therefore a large number of lives were indirectly saved. The *preventive* dose of the serum is 500 units, given on four occasions at intervals of one week, subcutaneously.

TUBERCULOSIS

A serum introduced by Marmorek has had considerable trial, but there seems little reason for regarding it as a serious contribution to the therapeutics of this infection. Nor can much more be said, in the opinion of the majority of observers, for the various forms of "tuberculin" that have been exploited very fully during the past few years. Be this as it may, there is very much less tuberculin therapy now being practised than was the case even ten

years ago. There are three types of tubercle antigen available for inoculation purposes—(a) *Tuberculin* (several varieties—Koch's, Denys', Beraneck's), an extract of the bacillus with or without its toxins; (b) *Bacillary emulsion*, a bacterial vaccine, and made like microbic vaccines generally; and (c) *Sero-vaccine*, a sensitised vaccine made like the sensitised vaccines described on p. 26. The bacillary emulsion is perhaps the favourite form of the remedy. Until quite recently, however, the "vaccine" in common use was Koch's tuberculin T.R. (*T. ruckstand*, "new tuberculin").

Omitting the views of enthusiasts, it is generally agreed that there are certain cases of tuberculosis in which tuberculin treatment is inadvisable—those who are markedly febrile, and especially when the pyrexia shows considerable fluctuations; those who have only just come under observation; and those who cannot remain under skilled observation during the treatment. It is also generally agreed that the most favourable cases for treatment are those in which retrogressive changes have already begun in the infected tissues. But to say this is equivalent to saying that the case is, as a rule, already improving, and that therefore the tuberculin may get credit which really belongs to time, the patient's natural resources, and whatever non specific measures are also being employed.

To administer some form of tuberculin to desperate cases—desperate from the advanced state of the patient's infection, or from the generalised or fulminating character of the disease-process—can only be justified on the ground that it possesses psychic value for the patient's friends, and perhaps assists *euthanasia*.

Perhaps the best types of case to choose for the method are lupus, adenitis, lesions of bones and joints, and tuberculosis of the urinary tract.

There is very great diversity of opinion as regards *dosage*, both in relation to the size of the injection and the frequency of its administration. Most practitioners steer their course between the heroic doses recommended by certain enthusiasts and the minute doses of another school and no doubt thereby show greater wisdom. If there be nothing about the case to indicate more than the ordinary caution, a common dose to begin with is $\frac{1}{200000}$ mgr. (T.R.), and this dose may be given at weekly intervals for 4 to 6 doses. A second series of doses of strength $\frac{1}{100000}$ mgr. may follow; then a third series of $\frac{1}{50000}$, and so on, until $\frac{1}{10000}$ mgr. is reached, beyond which dose it is not advisable to proceed. "Reactions" are not to be aimed at, whether general or focal. If either occurs, the next dose should not be increased, and the time-interval may be increased a little. These remarks apply to the usual—subcutaneous—route, the oral use of the antigen having nothing to recommend it.

TYPHOID AND PARATYPHOID FEVER

There is no antiserum at present available for which any good claim has been established, despite the sometime use of one in France, introduced by Chantemesse. Vaccine may be used for curative purposes either as a routine, or because the case is tedious in its course. The vaccine should be specially made for each patient, and should, by preference, be autogenous. Sensitised

typhoid vaccine has also been used. There does not yet appear to be good evidence that curative vaccine influences materially the course or the mortality of the disease. As regards dosage, here too there is considerable latitude in choice; some observers give small doses, *e.g.* 10 million bacilli on alternate days for 6 doses, to be repeated after an interval of (say) 1 week; others give doses as large as 100 to 200 million bacilli, and repeat them after 7 to 10 days' interval. This lack of uniformity in practice is probably due to too little consideration being given to the stage of the disease-process at which the treatment is tried.

The *prophylactic treatment* of typhoid fever by typhoid vaccine has been definitely proved to be successful, if reliance may be placed upon the recently published Army statistics. There is abundant evidence that the immunity conferred, though relative rather than absolute, is definite, and that it lasts certainly for a couple of years. If the vaccine be given in two doses, with an interval of 4 or 5 days, both the local and the general reaction are considerably diminished. The vaccine is usually made up to include *B. typhosus*, *B. paratyphosus* A, and *B. paratyphosus* B. The actual composition of the vaccines to be obtained from stock varies somewhat, but most of them contain 1000 million (mixed) bacilli in the first dose, and 2000 million bacilli in the second dose. The vaccine should be freshly prepared, and several different strains of bacilli should be utilised in their manufacture.

THOMAS HORDER.
JOHN MATTHEWS.

SECTION II

GENERAL INFECTIOUS DISEASES

A. BACTERIAL DISEASES

TOXÆMIA; SEPTICÆMIA; PYÆMIA

THE main results of the invasion and infection of the body by micro-organisms are discussed in the section upon infection and immunity. It is important to distinguish clearly between "invasion," "infection" and "intoxication," and the reader is referred to the section mentioned for the consideration of these several processes. The present article deals more particularly with the clinical and clinico-pathological effects of infection by the so-called pyogenic micro-organisms.

I. TOXÆMIA

This term is applied to the condition of a patient who is absorbing into the tissues and circulation toxins elaborated at some local site of microbial infection. The diseases caused by the specific microbes of diphtheria and tetanus are examples of toxæmia, the sites of infection being in the former disease the fauces or larynx, and in the latter disease the damaged tissue about a wound or abrasion. Erysipelas is a good example of toxæmia, set up by the specific dermatitis induced by infection of the skin with *S. pyogenes*. The symptoms of toxæmia are variable, and depend upon the special affinity that the toxins concerned have for certain tissues or organs. There are, therefore, general symptoms common to many microbial infections: fever, rigors, malaise, vomiting, pains in the back and limbs, headache, sweating, etc.; and special symptoms, such as are manifested by an affinity of the toxin for nerve structures (paralyses, spasms, delirium, etc.), or for the heart (arrhythmia, tachycardia, cardiac asthenia, etc.), and others.

II. SEPTICÆMIA

Septicæmia is a condition in which the infecting microbe transgresses the tissue barrier at the site of local infection and invades the blood stream, multiplying therein, and thus continuing the infection in a general manner. The mere existence of the microbe in the blood stream is not to be considered as necessarily constituting a true septicæmia. Thus we know that during the first few days of an attack of typhoid fever, of pneumonia, and of certain other diseases, the specific microbe can very often be isolated from the

circulation by blood culture. The more thoroughly the investigation of microbic infections by blood culture is undertaken, the more patent it becomes that at some stage or other the infecting organism exists in the circulation. Bacteriæmia is a convenient term by which to express the (temporary) existence of micro-organisms in the blood stream in other states than true septicæmia.

There are two main conditions of septicæmia in so far as this is related to the local infection. (1) The local infection may be obvious, the septicæmia clearly resulting from this; or (2) no local infection may be discoverable, or the local infection may be, at best, merely surmised. This second form of septicæmia was formerly termed "cryptogenetic." Even at a careful post-mortem examination the source of local infection may not be manifest in some of the cases illustrating this type of septicæmia.

The microbes chiefly concerned in septicæmia are *Staphylococcus aureus*, *Streptococcus pyogenes* (vel *hæmolyticus*) and the *pneumococcus*. Much less commonly the gonococcus, Pfeiffer's bacillus and *B. pyocyaneus* perform this rôle.

The local infections tending to lead to septicæmia are chiefly concerned with the throat (streptococcus), the uterus ("puerperal fevers"), the subcutaneous tissues of the hand and foot (infections during operations and post-mortem examinations, septic wounds, etc.), and the site of surgical operations (post-operative septicæmia).

Symptoms.—The symptoms in septicæmia vary much; there is also great variation in the intensity and course of the disease. Some of the worst cases from the point of view of prognosis are those in which physical signs are conspicuous by their absence, whether as regards the site of the local infection or as regards the development of secondary lesions (thromboses, visceral inflammations, etc.). Thus, in a case of puerperal septicæmia, if a careful examination of the pelvic organs reveals no defect in the uterus or its adnexa, and if no signs of local concentration of the infecting agent be found elsewhere, the case is likely to be one of great anxiety, and recovery is unlikely.

The symptoms include pyrexia, usually considerable in degree, and most often intermittent in character. Rigors are not uncommon, though by no means constant. The patient is generally free from pain and local discomforts, but feels exhausted and very ill. The mental state is usually normal; in some cases the outlook is disproportionately optimistic. Sweats are common, especially if the pyrexia is markedly intermittent. Diarrhœa may occur. Some degree of general abdominal distension is common. The spleen may be palpable. The pulse is quickened, the pulse tension lowered, and there may be subjective cardiac disturbances related to the toxic myocarditis which is an invariable result of the main pathological process. A progressive hæmolytic anæmia is one of the most striking features in most septicæmias, both clinically and upon examination of the blood. A steady decline is observed in the number of red cells and in the hæmoglobin content. The leucocytes vary a good deal, and their number constitutes a helpful point in prognosis: the smaller the count the worse the outlook. Loss of weight is not a noticeable symptom, except in cases which become "chronic," nor must the absence of this feature lead, of itself, to a favourable view as to the outlook. Erythematæ are often seen, especially in cases due to streptococcus infection; they are prone to be evanescent. Joint pains

and swellings are also common, and these not seldom disappear without any focal abscess formation.

Prognosis.—The prognosis is serious in all cases of septicæmia, though less so now than formerly. This is partly because, as the result of the earlier and more extensive use of blood cultures, more cases are recognised, and partly because the exploitation of immune therapy has, no doubt, added a useful element of treatment in many instances of the disease. Of serious import are the following: rigors, the absence of signs of the local infection, the absence of a definite leucocytosis, rapid progression in the associated anæmia, early dilatation of the heart, vomiting and delirium or stupor.

III. PYÆMIA

When septicæmia is complicated by the formation of multiple abscesses, or of multiple foci of tissue necrosis, the clinical condition is conveniently spoken of as pyæmia.

All pyæmic patients are septicæmic, but not all septicæmic patients are pyæmic. Some septicæmias tend to be pyæmias from the first, in other cases there is a late development of the pyæmia after a period of simple septicæmia lasting for days or, it may be, weeks. In the great majority of cases of pyæmia the primary infection is quite obvious.

There are three types of pyæmia according to the anatomical distribution of the primary infection in relation to the circulation.

1. *Systemic venous pyæmia*.—This is the form which is seen in osteomyelitis due to *Staphylococcus aureus*, in suppurating wounds (staphylococcus, streptococcus, *B. coli*, etc.), in suppurations of the urinary tract, and in suppurating dermatitis and cellulitis. The metastatic abscesses form in the lungs, kidneys, perirenal tissues, joints, bones, and, less often, in the heart wall and in the brain. The symptoms are those of a severe septicæmia together with those of the disease-processes set up by the focal events just referred to. Some of the cases are of long duration, and when this is so the patient is apt to become very emaciated.

2. *Portal pyæmia* (suppurating pylephlebitis).—This is the form of pyæmia resulting from certain pyogenic infections in the alimentary tract—rectum, colon, appendix, gall-bladder and elsewhere. The microbic infection follows in ascending fashion the radicles of the portal vein, setting up a septic thrombosis and ultimately causing multiple abscesses in the liver. The symptoms are those of a severe febrile illness with acute or subacute abdominal signs, moderate jaundice, and an enlarging liver. The diagnosis is sometimes difficult, but when indubitable the prognosis is extremely grave. The micro-organisms concerned are generally of the coliform group, or streptococcus; mixed infection is not uncommon.

3. *Arterial pyæmia*.—This form of pyæmia is seen in infective endocarditis, with which disease it is, for the most part, identical. The focus of primary infection, so far as the pyæmic process is concerned, is the endocardium, and especially of the valves, where colonisation of microbes takes place, and whence innumerable septic emboli proceed into the arterial system. Seeing that in the great majority of the cases this focus occurs on the left side of the heart the emboli, if they set up metastatic areas of infection, do so in organs and tissues supplied by the systemic vessels: spleen, brain, kidneys,

limbs, etc. In the less common instances, where the endocarditic focus is on the right side of the heart, the infection being grafted upon a congenital lesion, the emboli lodge in the pulmonary vessels, producing multiple infarcts in the lung, usually with associated pleurisy.

The microbes most often causing infective endocarditis are organisms of feeble virulence (streptococci of the salivary and faecal groups); this fact accounts for the infrequency of true suppuration in the infarcted areas occurring in this disease. When, however, the endocarditis is due to such virulent microbes as *Staphylococcus aureus* and *Streptococcus pyogenes*, abscess formation does occur in the infarcts.

Treatment.—The treatment of this group of infective processes, and especially of the cases of septicæmia and pyæmia, not infrequently taxes the practitioner's resources to the utmost. The widest possible view should be taken of the therapeutic position, but all highly experimental measures, of which a large number frequently come up for review in connection with the more severe or tedious cases, should be regarded with a healthy scepticism. The programme of treatment should be considered under four heads: general measures, drugs, specific therapy and surgery.

1. *General measures.*—These include rest, ample nutritious diet, abundant fresh air, the control of fever by hydrotherapeutic means, and the maintenance of a cheerful outlook in the patient and in his medical attendant. The nursing of these "septic" patients is of great importance, and experience of similar cases is a great asset.

2. *Drugs.*—Drugs having reputed bactericidal action are numerous, but experience does not, even when the chemical agent is exploited generously and by the intravenous route, justify any degree of confidence in them. There has recently been a vogue for the intravenous use of mercurochrome in cases of septicæmia, but the results have not, in the practice of the writer, proved at all promising. Perchloride (and more recently salicylate) of mercury, given in 5 c.c. doses of a 0·05 per cent. solution, and repeated daily if necessary, until salivation occurs, are two alternatives if the physician wishes to make trial of such a method. The intramuscular injection of colloidal manganese in the staphylococcus cases, and of colloidal silver in the streptococcus cases, has yielded some apparent good results, but these drugs must be considered as still on probation.

To control the progressive anæmia, over and above the general measures, arsenic is perhaps the most useful remedy; it may be given conveniently as sodium cacodylate, gr. i, once or twice daily, in the form of intramuscular injection. The writer often combines it with nucleic acid, a useful stimulant to leucocytosis, in the following formula:

R Sod. cacodylatis, gr. ii.
Ac. nucleici (sat.) ad ℥xv.

3. *Specific therapy.*—For a detailed account of the measures that may be used in order to combat the infection by way of immune therapy, the reader is referred to p. 24. These measures are, it goes without saying, of much greater theoretical importance than those which act non-specifically. Unfortunately our knowledge of efficient specific remedies grows very slowly, and there are many gaps and guesses in it. All the same, careful consideration should be given in every case to the nature of the infection and to the

question if some form of specific treatment, whether by immune serum or by vaccine, or by both, may not be of service.

4. *Immuno-transfusion and Simple Transfusion.*—These measures may be helpful in particular cases.

5. *Surgery.*—All abscesses developing in the course of a pyæmia must be drained forthwith, either by aspiration or by free incision.

TERMINAL INFECTION

Micro-organisms which are found in the tissues in the course of a post-mortem examination are related to them in four different ways. (i.) They may be the primary infection leading to the disease-process which causes death. (ii.) They may be present as secondary infections, in association with the primary infection, and they may or may not be largely responsible for the death of the patient. (iii.) They may be present as a "terminal infection," the disease-process from which the patient suffered being not itself manifestly of microbic origin, but one tending to lower the tissue resistance to infection. The terminal infection in these cases generally, as the name implies, precipitates the lethal event, or actually causes it. (iv.) They may be present merely as an agonal or sub-mortem invasion, or even as a post-mortem invasion. It is necessary carefully to distinguish between the last two of these relations. The mere isolation of organisms from certain tissues (*e.g.* the mucoid material of the middle ear) in the post-mortem room does not prove that they were present in these situations during life, still less that they were operative by way of actual infection. It is even doubtful if the cultivation of organisms from the blood of the heart, or from the cerebro-spinal fluid, after death, gives evidence of infection during life, though some authorities consider that it does. Much depends, of course, upon the conditions at the time of the investigation.

Terminal infection does certainly occur, however, in well-recognised form, and quite distinct from sub-mortem invasion. The organisms most often responsible for the condition are the less virulent strains of streptococci (*S. salivarius* and *S. faecalis*), the coliform group, staphylococci and the tubercle bacillus. *B. proteus* and *B. aerogenes capsulatus* are also found to operate in this manner at times.

The disease-processes in which terminal infection frequently occurs are cirrhosis of the liver, granular kidney, diabetes, leukaemia and morbus cordis. There is a latent form of infective endocarditis (most often streptococcal in origin) which is also of the nature of a terminal infection. Serous membrane tuberculosis, and especially peritonitis, is quite common in cirrhosis of the liver. Many of the patients in whom this terminal infection occurs are so ill at the time the event arrives that it frequently goes undiscovered, partly because their responses to infection are feeble and partly because clinical examination is difficult.

STREPTOCOCCUS INFECTION

The streptococci form a group of micro-organisms in which the different members vary greatly in virulence. They also vary in their morphological

and cultural features and in their biochemical reactions. There is, therefore, no little difficulty experienced in any effort at successful classification. One result of the efforts that have been made by various workers is an unfortunate confusion in nomenclature. Broadly speaking, there are two main types of the microbe. (1) There is the highly virulent type, called *Streptococcus pyogenes* (which it is generally agreed is identical with *S. erysipelatosus*), to which the alternative name *Streptococcus hæmolyticus* has more recently been applied, on account of its property of hæmolyzing when cultivated on blood-agar. (2) And there is the more feebly virulent type, including the variants *S. salivarius* and *S. faecalis* of some authorities, and *S. viridans* and *S. mucosus* of others. The first type is usually seen in long and curling chains when recently isolated, and the second is usually seen in short chains of two, four, or some number of relatively few members.

S. pyogenes (vel *S. erysipelatosus*; *S. hæmolyticus*) is the causative microbe in erysipelas, in acute abscess formation, in acute cellulitis and lymphangitis, in severe operation and post-mortem infections when these are of streptococcus origin, and in the more virulent streptococcus infections complicating influenza, scarlet fever, and some other specific fevers.

S. salivarius and *S. faecalis* (vel *S. viridans* and *S. mucosus*) are found in association with pyorrhæa alveolaris, with secondary streptococcus infection in rheumatic fever, with arthritis occurring in connection with focal infections, and with most chronic and subchronic infections of streptococcus origin. The streptococci found in the heart valves, and in the blood stream in cases of subacute bacterial endocarditis, are for the most part of this nature.

The clinical results of streptococcus infection vary according as the infection is by the first or by the second of these types of the microbe. In infection by *S. pyogenes* the disease-process is usually acute and often fulminant. Septicæmia results not infrequently, and pyæmia is not uncommon. If endocarditis results from the infection and embolism occurs, the infarcts suppurate. In infection by *S. salivarius* and *S. faecalis* the disease-process is prone to be subchronic, or at most subacute. Septicæmia is uncommon, except in association with endocarditis, in which condition embolic infarcts proceed to coagulative necrosis, but not to abscess formation.

Secondary infection by streptococci (most often of type (2)) is a very common event in rheumatic fever. There are some authorities who consider that this disease is itself an expression of streptococcus infection (see article on Rheumatic Fever, p. 292).

Treatment of streptococcus infection is dealt with in the article on Specific Therapy (p. 44).

ERYSIPELAS

Definition.—An acute specific disease, due to infection of the skin by *Streptococcus pyogenes*, leading to local dermatitis and constitutional symptoms, of which fever and toxæmia are the most prominent.

Ætiological Factors.—Infection by *S. pyogenes* is certainly the essential factor. The more carefully the cases are examined and the patients questioned the more certain it becomes that in the great majority of them some abrasion,

it may be very slight, is present in the skin at the site of infection. This abrasion may be an actual wound, whether of a surgical operation or not. More often it is less apparent—a scratch, an insect bite, the chafing of a foot by a badly fitting shoe, etc. Contact by the human hand during the infliction of these slight injuries is not uncommonly a feature in the case.

Bad hygienic conditions seem to contribute to the incidence of the disease, such as defective sanitation and ventilation in public institutions. Formerly the disease was rife, almost epidemic, in hospitals, and chiefly amongst the surgical patients. During the puerperium a woman is prone to erysipelous infection.

The disease is said to have a seasonal incidence (January to May), and Newsholme showed that the curves of its prevalence conformed somewhat to those of scarlet fever and acute rheumatism. We do not know, however, the reasons for this.

The disease is more common in women than in men, perhaps because of the puerperal cases. Alcoholism is a great predisposing factor, and appears to determine recurrences of the infection in certain liable individuals. Gout is another factor rather commonly present in the cases.

Symptoms.—There is an incubation period of some 2 to 5 days. The onset is usually abrupt, often with a rigor (or a convulsion in little children) and a sharp rise of temperature— 102° to 103° F. In severe cases the patient suffers from malaise, aching pains about the body, and headache. The headache may be so severe as to mislead the observer into thinking there is some cerebral infection (*e.g.* meningitis). Delirium may be present, rendering the doubt still greater. If, as is sometimes the case, the local lesion is not apparent to the patient, or is not discovered on examination, the case may be very obscure indeed. But in the majority of instances there is a feeling of heat, tightness, or pain at the site of infection, leading to the recognition of the dermatitis. The inflammation usually appears during the second day—the skin is red, hot to the hand, slightly raised, with a spreading margin upon which there may be minute vesicles containing clear or turbid fluid. The area spreads rapidly, and becomes œdematous, the degree of this latter effect varying with the situation of the inflammation. If this is the face, the œdema is marked, especially if the eyelids and lips are involved: the whole face may then be greatly swollen and the patient's features scarcely recognisable. On the limbs there is frequently present some degree of lymphangitis—red streaks, more or less continuous, stretching upwards towards the groin or axilla, in which situations the lymph glands are frequently swollen, painful and tender. When the dermatitis is fully developed the vesicles already referred to may become blebs of considerable size.

In less severe cases the constitutional disturbance may be much milder, but so long as the diagnosis is definite the development of serious symptoms must always be regarded as possible, especially if the patient be elderly or debilitated.

The course of the disease varies considerably. If uninterrupted by specific treatment it lasts from 1 to 3 weeks.

Complications.—Albuminuria is not uncommon in all cases in which the temperature is high. Signs of nephritis supervene in not a few severe cases; when this is so the question should arise as to the previous integrity of the

kidney. Oedema of the larynx is a rare complication ; spread of the inflammation from the face to the orbit is less uncommon, and in this event meningitis is to be feared. Pneumonia sometimes occurs, again in debilitated, elderly or alcoholic subjects. Septicæmia, it may be with a fulminating form of infective endocarditis, is another serious possibility.

Diagnosis.—Reference has already been made to those cases in which the real nature of the disease is masked by the severity of the general invasion symptoms and the non-discovery of the skin lesion. Apart from such instances the diagnosis is rarely difficult if the examination be carefully conducted. The presence of even the smallest vesicle in association with a suspicious red area of skin should be investigated by piercing it with a very fine capillary glass tube and filming and cultivating the contents, even if these seem to the naked eye to be almost clear fluid. The discovery of a long chained streptococcus in the films not only establishes the diagnosis, it enables the practitioner to adopt prompt specific measures of treatment, and gives him material for the preparation of a vaccine, should the use of this be deemed desirable.

Prognosis.—The disease is very fatal in infants and in old people. It is dangerous in alcoholics, nephritics and the plethoric gouty type of patient. In all others the outlook is good. But septicæmia is of grave omen, and if associated with endocarditis it is always fatal. Meningitis, following orbital cellulitis and ophthalmia, is scarcely less lethal. The occurrence of acute nephritis, of cellulitis of the neck or of pneumonia, though all of these give rise to great anxiety, does not render the case hopeless.

Treatment.—**PROPHYLAXIS.**—The patient should be isolated, and the greatest care should be taken in nursing, as well as in all the examinations made by the medical attendant. The sick-room should be large and well ventilated.

CURATIVE.—(i.) *Local measures.*—Various applications are in use. Perhaps one of the best is ichthyol ointment (25 per cent.), though this has the disadvantage that it somewhat obscures the local signs. A lotion of perchloride of mercury (1 in 4000), continuously applied on linen strips, is free from this objection. The old method of painting the spreading edge of the dermatitis, and the healthy skin around it, with tincture of iodine, has many advocates. In erysipelas of the face the eyes should be protected by a few drops of argyrol (5 per cent.) applied two or three times in the 24 hours.

(ii.) *General measures.*—Full diet is allowed, provided it can be digested. In severe cases ample fluid must be given, as to all “septic” diseases. Volatile stimulants (brandy) are indicated whenever the constitutional symptoms are severe and the heart flags. Febrifuge drugs are best avoided, the temperature being controlled by hydrotherapeutic or arotherapeutic methods. There is probably no drug that possesses a “specific” value in the disease, though the writer usually follows the lead of those enthusiasts who strongly recommend perchloride of iron. If this be used it should be given in $\text{m} \times \text{x}$ doses, very freely diluted, every 4 or 6 hours.

(iii.) *Immune therapy.*—The prompt use of univalent *S. pyogenes* serum, followed by small doses of *S. pyogenes* vaccine, probably constitutes the best method of exploiting specific measures of treatment. For details of these see p. 46.

PNEUMOCOCCUS INFECTION

The *pneumococcus* (*Diplococcus pneumoniae*; *Micrococcus lanceolatus*) is a small oval coccus, measuring about 1μ in its long diameter, generally arranged in pairs, but also seen as single elements, and often in short chains when examined in preparations made direct from tissues or secretions. The organism is Gram-positive and possesses a capsule. It is found in healthy saliva and in the respiratory passages of healthy individuals. Outside the body it is not often found, its viability being low; sunlight kills it in one and a half hours.

Types of the pneumococcus.—It has been realised for a long time that different strains of the organism exist, of varying virulence. R. Cole and others, working at the Rockefeller Institute, have attempted a "grouping" of these strains, basing their results upon differences in immunological reactions. They described four types in relation to pneumonia. Types I. and II. together accounted for 60 per cent. of the cases studied, and were of relatively high virulence, yielding a mortality of 25 to 30 per cent. Type III. accounted for 10 to 15 per cent. of the cases, with a mortality of 50 per cent. Type IV. comprised the remainder (25 per cent.) of the cases, with a mortality of about 12 per cent. The pneumococcus found in the healthy mouth conformed generally to Type IV. Lister, working along Cole's lines in South Africa, found that at least 30 per cent. of his cases conformed to a type not described by Cole. This work, admittedly subject to extension, has very important bearings upon the serum treatment of pneumococcus infection.

Relation of the pneumococcus to pneumonia and allied infections.—The pneumococcus is regarded as being the primary infective agent in acute lobar pneumonia, in most cases of acute broncho-pneumonia in children, and in many cases of empyema. Pneumonia may be considered as a systemic pneumococcus infection with the production of focal lesions in the lung. The organism can, in the majority of cases, be isolated from the systemic circulation by blood culture during the first 3 or 4 days of the disease. This fact also holds good for those forms of acute pneumococcus infection in which focal lesions do not appear in the lung, but in the pleura or elsewhere (see below). The factors which determine the invasion of the blood stream by an organism which is a normal inhabitant of the bronchial tract are equivocal; they are considered to be a lowering of the tissue resistance and (or) a rise in virulence of the organism. Cole's work makes it likely that in some cases at least, the invasion may be by a more virulent strain of the germ than that which occurs in the body in a saprophytic form.

The rusty sputa of pneumonia usually reveal the pneumococcus clearly when "filmed" and when cultivated. Lung puncture in pneumonia also yields the pneumococcus. The existence of positive blood cultures has already been referred to. The organism has been found in herpetic vesicles developing during the disease, and it is not very uncommon to find it in the urine under similar conditions.

Pneumococcus infections other than pneumonia. *Pericarditis* is sometimes regarded as a direct spread of the infection from the lung by means of the

lymphatics, but it is quite as likely to be an infection from the blood stream. *Endocarditis*, a very serious form of infection, is of the "ulcerating" type (see p. 825). *Meningitis*, another grave focal infection, being highly purulent in character, is perhaps the most fatal form of pyogenic infection of the meninges. *Peritonitis* occurs either as an isolated infection or, less often, as a complication in pneumonia; it is less uncommon in children than in adults. *Otitis media* is perhaps the commonest of all acute pneumococcus infections in children, if we except (broncho-) pneumonia. Of 46 cases of primary pneumococcus infection in children, Netter found that this disease was present in 29, suggesting the mouth or nasal cavities as the source of invasion. *Arthritis*, again chiefly in children, is a somewhat rare manifestation of the same infection. A true pneumococcus *nephritis* occurs, in most cases a complication of pneumonia or of empyema; hæmaturia is usually a prominent symptom. This catalogue by no means exhausts the known series of pneumococcus infections: few if any organs or tissues are wholly exempt.

Pneumococcus septicæmia occurs somewhat rarely (apart from endocarditis and its associated pyæmia), and there may be no obvious initial lesion. A few cases of puerperal septicæmia are of pneumococcus origin.

The treatment of pneumococcus infection, as such, and apart from the disease-processes consequent upon it, is discussed on p. 42.

GONOCOCCUS INFECTION

The *gonococcus* is a small diplococcus, having its two adjacent surfaces flattened or slightly concave, with a small oval interval between them. It is Gram-negative in its staining reaction, and, when seen in exudates and in tissues, it is very largely intracellular in distribution—a helpful feature in diagnosis. The gonococcus is a very strict parasite, being dependent for spread upon direct transference from host to host. It probably does not live outside the human body for many hours.

MODES OF INFECTION.—Sexual intercourse is by far the most common and important mode of infection. Contamination of the conjunctival sac of the newborn infant by infected vaginal secretions is another important way by which the organism is transmitted. Least often, accidental contamination sometimes occurs from infected material, either of the vagina in little children or of the eyes in children or adults.

CHARACTERS OF GONOCOCCUS INFECTION.—Perhaps the most peculiar, and certainly the most important, feature of gonococcus infection is its obstinate persistence. This organism is, relatively to many others, responsible for few deaths as the direct result of acute infection, but this low mortality ratio is compensated by a high degree of morbidity incidence. Once the invasion of gonococci has led to definite tissue infection, this is prone to become very intractable, resisting the most persevering and thorough efforts at defeating it. Gonococcus infection is too often measured by years rather than months, though there are oftentimes intervals of comparative freedom from toxic effects upon the infected organs. Such a lesion as acute *iritis*, for example, may appear in the subject of old gonococcus infection, several years after the primary invasion, and the evidence that the inflammation is due to this

source may be unimpeachable. The writer has known this to happen fourteen years after the primary urethritis. But it is sometimes very difficult to exclude a recurrence of the initial infection.

Once the inflammatory response to infection has passed the urethral stage, it is often very difficult to obtain direct bacteriological evidence of the nature of a suspected gonococcus infection. The number of organisms concerned may be small, they are often deeply embedded in the tissue spaces and cells, and they may not be shed into any effusions or secretions that chance to be available for clinico-pathological investigation. As yet, the indirect diagnostic methods (agglutination, complement fixation, etc.) are scarcely of sufficient trustworthiness to supply the data left lacking by the negative direct bacteriological results referred to.

Secondary infection, especially by staphylococci, streptococci and diphtheroid organisms is very common.

CLINICAL RESULTS OF GONOCOCCUS INFECTION.—These may be considered under three headings: the results of the primary infection, the results of the zone of immediate spread, and the results of general dissemination.

(i.) *The results of the primary infection.*—These are acute and chronic urethritis (with gleet); acute and chronic vaginitis, cervicitis and cervico-endometritis; and conjunctivitis. These lesions do not come under consideration in a text-book of medicine.

(ii.) *The results in the zone of immediate spread.*—These include peri-urethritis (and abscess), prostatitis, epididymitis and vesiculitis in the male; salpingitis with salpingo-ovaritis in the female; and cystitis in both sexes. In both sexes, again, the peritoneum may become infected locally, a much more common and important event in females than in males, as might be expected for anatomical reasons. Indeed, in women, varying grades of pelvic peritonitis, with plastic inflammatory changes, constitute perhaps the greatest bane of gonococcus infection, both from the physician's and the surgeon's point of view. Chronic ill-health, adhesions that permanently handicap the functions of the pelvic viscera, and acquired sterility are amongst the disabilities accruing therefrom. In the male, late results of infection are scarcely less serious by way of Nemesis: urethral stricture, chronic prostatitis, "ascending" pyelitis and secondary coliform infection of the urinary tract.

(iii.) *The results of general blood infection.*—These may be subdivided into a true septicæmia and pyæmic manifestations.

(a) *Septicæmia*, though rare, has been definitely established clinically and clinico-pathologically, both in America (Thayer, Blumer, Ahmann) and in England (Horder). Endocarditis, of a progressive and "ulcerating" form, is present in most of the cases, and, though recovery has taken place in one or two known instances, the disease is generally lethal. Diagnosis turns upon the isolation of the organism from the blood stream in a case presenting the clinical features of septicæmia.

(b) *Pyæmic manifestations.*—Of these the most important is *gonorrhœal rheumatism*, with associated arthritis, fibrositis, teno-synovitis and allied lesions (see p. 1242). Gonorrhœal rheumatism must be considered to be a form of gonococcus pyæmia, at least when seen in its acute and sub-acute types. The organism has been recovered from the affected joints in a large number of the cases, and in a few from the blood stream as well as

from the joints. *Spondylitis deformans* has been traced to (old) gonococcus infection in a considerable proportion of cases.

Pericarditis and *pleurisy* have both been described as remote results of gonococcus infection.

Iritis, already referred to, is prone to be of the recurrent type. It is often ascribed to syphilis when it is much more probably of gonorrhoeal origin.

Treatment.—See general section on Immune Therapy (p. 39).

THOMAS HORDER.

TYPHOID FEVER

Synonyms.—Enteric Fever; Gastric Fever.

Definition.—An infectious fever characterised by prolonged pyrexia of distinctive type, an eruption of rose spots, enlargement of the spleen, abdominal discomfort and bowel disturbance. Ulceration of the agminate and solitary lymphoid glands of the small intestine and enlargement of the mesenteric lymph glands and spleen are distinctive lesions. Typhoid is a septicæmia caused by the *Bacillus typhosus* of Eberth, which during the septicæmic stage is carried to all parts of the body and settles and multiplies in the agminate glands (Peyer's patches) of the intestine, the mesenteric lymph glands, spleen, liver, gall-bladder and bone-marrow. Those organs which have excretory ducts, e.g. the liver and gall-bladder and the kidneys, as well as the intestinal tract, form the chief channels of elimination.

Ætiology.—The *Bacillus typhosus* is a flagellated, rod-shaped organism, about 3 μ in length and 0.6 μ in thickness. It is actively motile and easily grown on artificial media. It belongs to the enteric group of organisms, a group which includes also the paratyphoid bacilli. It grows best at blood heat and is quickly killed by boiling water, and within 15 minutes by exposure to a temperature of 60° C. (140° F.). It may survive for a considerable time in ice, and also in fresh or salt water. It resists ordinary drying so that typhoid may be propagated by dust or by garments and bed-clothes soiled by typhoid excreta. It has been found alive in the mantle-cavity and intestines of oysters, mussels and other shell-fish which have lived in sewage-contaminated water. It grows freely in butter and in milk.

The toxins are mainly intracellular. Inoculation of animals with virulent cultures produces a septicæmia without the characteristic intestinal lesions seen in man. Even in the latter the disease at times occurs without producing intestinal ulcers. The serum of patients has a specific agglutinative influence on cultures of the organism, a fact which is made use of in diagnosis, and at certain stages the bacillus can be cultivated from the blood. In man, infection is introduced by the alimentary tract, and is derived, directly or indirectly, from a human source—typhoid fever not being a disease of the lower animals.

Typhoid occurs in all parts of the world, but is most rife in tropical and subtropical countries. In Great Britain it is most prevalent in the months of September, October and November; in other countries the maximum incidence corresponds to the warm season. A hot, dry summer increases the prevalence in the autumn. An epidemic recrudescence is believed to occur every 5 or 7 years. Rather more males than females are attacked,

and the greatest susceptibility is between the twentieth and twenty-fourth years. Infants are rarely infected; but the disease does occur in childhood, and is then likely to be overlooked. After the thirtieth year there is a progressive fall in its incidence. It is rare but not unknown in old age.

One attack confers immunity, which usually lasts for life, but second and third attacks have been reported. Where typhoid is endemic a proportion of the community acquires immunity without having passed through a recognisable attack. The supposed racial immunity of the Japanese, Indians and certain other peoples may in reality be acquired through infection contracted in childhood. Fatigue and overwork are powerful predisposing factors, and no condition predisposes so much as war to typhoid and paratyphoid infections, owing to the aggregation of susceptible subjects under conditions of defective sanitation, fatigue and exhaustion. Prophylactic vaccination has found its greatest triumphs under these conditions.

Propagation from the human source may be indirect or direct. Of indirect causes aerial infection, apart from the influence of wind-borne dust and of flies, is very doubtful. Drinking water contaminated by sewage is the most common cause of widespread outbreaks. Milk and other articles of food may act as vehicles of infection by becoming contaminated by a carrier. Watercress and green vegetables, eaten uncooked, also spread the disease. Amongst shell-fish, oysters, mussels, cockles and periwinkles are dangerous. Fomites, enema syringes, bedpans, etc., which have been soiled by typhoid excreta undoubtedly act as infective agents. Laboratory workers have been infected by their cultures.

Direct contagion plays but a small part in the production of epidemics, but assumes importance in causing localised outbreaks, infection being conveyed by the fæces, the urine, the vomit, discharges from abscesses and possibly by the sputa. The chief danger arises with mild and unrecognised infections. Strict attention to personal cleanliness and proper disinfection of excreta, soiled linen, feeding utensils, etc., go far to eliminate infection, and prophylactic inoculation is a great safeguard. Of convalescents from typhoid, a small proportion, about 5 per cent., continue to pass bacilli in the stools for months or years. These are known as intestinal carriers. They may appear to be quite healthy, or may suffer from periodic intestinal disturbance or from symptoms referable to the gall-bladder. Typhoid bacilluria occurs in 25 per cent. of the cases of typhoid, but is as a rule quite transitory, urinary carriers being much less common than intestinal carriers. Carriers are particularly dangerous when they happen to be engaged in handling food or milk.

The endemic occurrence of typhoid in certain localities is now attributed to the influence of human carriers rather than to the persistence of infection in the soil, although it is an undoubted fact that the typhoid bacillus may persist for a time and even multiply in sewage-infected earth.

Pathology.—The most characteristic lesions are in the small intestine. In the early stages the Peyer's patches are hyperæmic and swollen, the swelling attaining its height about the tenth day of the disease. The solitary follicles of the intestine are similarly affected and a diffuse catarrh of both large and small bowel may be present. Necrosis ensues in the inflamed lymphoid masses, and yellowish-brown sloughs are formed, the separation of which occurs during the third and part of the fourth

weeks. In some cases, slow resolution may possibly take place without necrosis or sloughing. The ulcers which result from sloughing of Peyer's patches are ovoid and lie along the long axis of the bowels. Those which arise in the solitary follicles are more circular. The edges of a recent ulcer are undermined, and the floor shows smooth muscular fibres, or sometimes the peritoneal coat. As the sloughs separate, perforation or hæmorrhage may ensue. Immediately above the ileo-cæcal valve irregular sinuous tracts of ulceration may be evident. Actual ulceration of the solitary follicles of the large intestine is rare. The ulcers of typhoid heal without contraction, and regeneration of the epithelial covering takes place. A slaty pigmentation, often punctate, may persist. The time required for healing is a week or ten days. When perforation occurs it is usually in the lower ileum, where ulceration is most intense. It may, however, happen in other situations such as the pelvic colon, cæcum, appendix, or, on rare occasions, the jejunum.

The mesenteric lymph glands, particularly those of the lower ileum, are hyperæmic and swollen. They rarely suppurate. The spleen is enlarged to twice or thrice the normal size. It is softer and redder than normal, and the Malpighian tufts may be enlarged. Infarction sometimes occurs, but rupture is rare. Parenchymatous degeneration occurs in the liver, and minute opaque areas of focal necrosis are scattered through its substance. The gall-bladder may become infected and cholecystitis result. Pylephlebitis is a rare complication due to infection from the bowel. Cloudy swelling of the kidneys is the rule, occasionally a parenchymatous nephritis ensues. In chronic urinary carriers inflammation of the renal pelvis or urinary bladder may be found.

The myocardium shows fatty and granular degeneration. Endocarditis is rare, but endarteritis may affect the aorta, coronary arteries and peripheral vessels. Atheroma is a sequel. Hypostatic congestion of the lung bases is the rule with, it may be, distinct broncho-pneumonic consolidation. Lobar pneumonia is uncommon. Gangrene, abscess or infarction of the lungs is rare. Ulceration of the larynx may occur, the ulcers being found in the neighbourhood of the arytenoid cartilages, or at the base of the epiglottis. Necrosis of the cartilages sometimes occurs. Zanker's vitreous degeneration of muscle, although not peculiar to typhoid, is particularly marked in this disease. It chiefly affects the straight muscles of the abdomen, the adductors of the thigh and the diaphragm. Rupture of muscle and hæmorrhage may ensue. Osteo-periostitis of the tibia, vertebrae and other bones may be due to primary infection with the typhoid bacillus or to secondary infections with other organisms. Superficial abscesses, degenerative changes in the central nervous system or peripheral nerves, and venous thrombosis are also sequels of typhoid infection.

Symptoms and Course.—The period of *incubation* averages from 10 to 14 days, but may be as short as 5 days or as long as 3 weeks. Symptoms are generally absent, but ill-defined malaise or, more rarely, gastro-intestinal disturbance may occur.

The *onset* of the fever is generally insidious with chilliness, lassitude, loss of appetite and muscular pains. Symptoms which are particularly suggestive are frontal headache, epistaxis, slight bronchitis and disturbing dreams. The tongue becomes furred, the mouth dry and the bowels loose or constipated. The patient may not take to bed for a day or two. The temperature

risers gradually, being a degree or more higher each succeeding night with morning remissions. By the end of the first week the patient's condition is very characteristic. The aspect is heavy and the cheeks are flushed. The lips and mouth are dry, and the dorsum of the tongue covered with a dirty white fur, the tip and edges being raw. The abdomen is slightly tumid, with gurgling in the right iliac fossa. The bowels are generally loose, several liquid motions like pea soup being passed in the 24 hours; sometimes, however, there is constipation. The spleen may be palpable. A characteristic feature is a moderately full but easily compressible pulse, the frequency of which is not increased in proportion to the temperature. The respiration is accelerated. The temperature will by now have attained a maximum of 103° to 105° F., still showing morning remissions of about 1° , and is unstable, reacting quickly to minor disturbances. The urine is high coloured and concentrated, and the skin usually dry. Thirst and headache are the chief complaints.

The rose spots usually make their appearance towards the end of the first

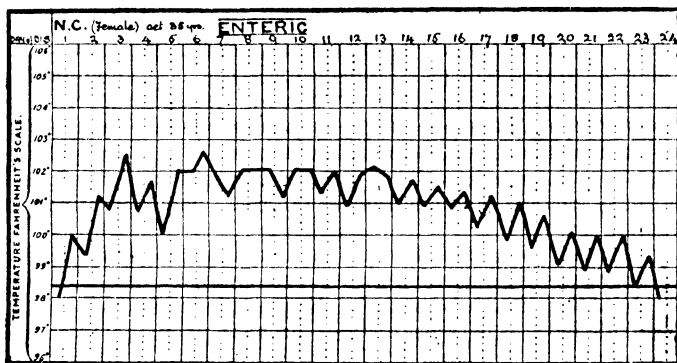

FIG. 1.—Typhoid Fever from the first day. Illustrating gradually rising temperature, a "continued" stage, and a typical lysis.

week, sometimes on the fifth day, more often between the seventh and twelfth. Each spot is a circular, slightly elevated papule of a pale pink colour from 2 to 4 mm. in diameter, disappearing on pressure. The rash should be sought for on the abdomen, the flanks, the sides of the chest and the back, which should always be scrutinised. The spots appear in successive crops, each one fading in 3 or 4 days, and leaving a transitory brownish stain. Often the eruption is scanty, a few spots only being seen; occasionally it is very profuse, and involves the limbs as well as the trunk. The face usually escapes. Minute sudaminal vesicles occasionally cap some of the spots. The eruptive period lasts from 10 days to 3 weeks. A profuse rash does not necessarily indicate a severe attack.

By the second week the fever (Fig. 1) has reached its fastigium or acme. The temperature maintains its level with slight morning remissions, the headache may abate, but prostration increases and the other symptoms are more severe. The lips become cracked, sordes accumulate on the teeth, the abdomen becomes more distended and diarrhoea is often a marked feature, the stools being liquid, yellow in colour, alkaline and foul. They may be

chocolate-coloured or red from admixed blood and small shreds of tissue, or actual sloughs may already be present. The evacuations are not accompanied by colic or tenesmus. The spleen is now larger. The pulse rate will have quickened to a frequency of 112 to 140. It is often dicrotic, and the heart sounds enfeebled. The bases of the lungs may now show signs of hypostatic congestion, and the respiration be more accelerated with slight lividity of the lips and face. Delirium of a muttering character disturbs the sleep, *asthenia* is very marked and muscular wasting rapid. The urine may be albuminous. Patients may succumb during this period from toxæmia, or towards the end of the first fortnight from perforation of the bowel or intestinal hæmorrhage.

During the third week improvement should occur, the temperature becoming more remittent in type, the morning reading falling more rapidly than that of the evening. The tongue cleans and appetite begins to return. During the fourth week defervescence may be completed, the temperature usually remaining at a subnormal level for some time. In severe infections, however, the third week is a period of increasing anxiety. The symptoms increase in severity and the patient may pass into the "typhoid state," lying on the back in a semi-stuporose condition, and tending to sink down into the bed. The pulse and heart sounds become more and more enfeebled, the pulmonary congestion increases, the extremities become blue and cold, subsultus tendinum appears, and the evacuations are passed unconsciously. Sometimes there is retention of urine. Extreme abdominal distension may supervene, and the occurrence of perforative peritonitis or of hæmorrhage from the bowel is more than ever to be dreaded. In such severe cases the fever may be prolonged through the fourth and fifth weeks before any signs of defervescence appear. They are not necessarily fatal.

Convalescence after a severe attack is always protracted. The temperature is at first subnormal, and remains in a very unstable state. The heart sounds remain enfeebled, and the pulse is often rather fast or easily quickened by exertion or excitement. The effort of standing and walking is difficult and painful. The appetite, however, is good, and the weight rapidly increases. The aspect gradually becomes less anæmic. Slight peeling of the skin, loss of hair, and ridging or furrowing of the nails is often noticeable. During this period the feet and ankles may show slight œdema, and cutaneous abscesses or localised bone abscesses may occur. Femoral thrombosis sometimes appears, and loss of memory may be noticeable.

Relapse.—Tendency to relapse is a marked feature, and shows itself in from 5 to 15 per cent. of the cases. The relapse may be intercurrent and occur during actual defervescence, but more commonly develops after an afebrile period of a week or a little longer. The symptoms of relapse are a repetition of those of the original attack, but generally in a mitigated form, the fever reaching its acme in a shorter time, and the whole duration being 10 days or a fortnight. The spleen enlarges again, a new crop of rose spots usually appears, and fresh ulceration of the bowel occurs. On occasions, the relapse equals or exceeds the original attack in severity, and may even prove fatal. Spurious relapses are recrudescences of fever during convalescence, of short duration, and unaccompanied by definite symptoms. Their explanation is often obscure.

The fact that typhoid fever may show great variations in its clinical characters, and in the severity and prominence of different symptoms, has

led to the description of many special types. It is noticeable, too, that different epidemics may differ much in their salient features.

Variations in onset.—The onset of febrile symptoms may be sudden, sometimes with rigors and vomiting. The temperature rises quickly, and delirium may supervene early. In such acute cases, death may occur during the second week, or the disease may gradually assume the ordinary type. In exceptional cases, pneumonia may mark and mask the onset, the attack commencing abruptly with consolidation of the lung. The true nature of the infection may be overlooked and only discovered at autopsy, or the pneumonia may subside and be replaced by the ordinary symptoms and signs of typhoid. This variety is known as *pneumo-typhoid*. The prominence of meningeal symptoms may lead to confusion with cerebro-spinal fever, and the differential diagnosis only be possible by examination of the cerebro-spinal fluid. Sometimes this is turbid and contains the typhoid bacillus, but more commonly it is under tension but clear, and the meningeal symptoms quickly subside after lumbar puncture, to be succeeded by the more typical signs of typhoid fever. The term *meningo-typhoid* is applied to such cases. Yet another occasional mode of onset is with a primary acute hæmorrhagic nephritis (*nephro-typhoid*). When acute gastro-intestinal symptoms signalise the invasion, appendicitis or irritant poisoning may be simulated.

Variations in course.—There is an ambulatory form in which febrile disturbance is generally, although not invariably, slight, and the patient continues about during the whole or the greater part of the illness. Some such cases end in recovery; but they often run a very severe course, the patient taking to bed about the end of the second week with aggravated symptoms, or succumbing to hæmorrhage from the bowel, perforation, acute delirium or myocardial failure. Mild and abortive forms of typhoid also occur in which the fever is insignificant, or, after a well-marked onset, ends in a rapid defervescence between the eighth and fourteenth day. An afebrile form is known, and is said particularly to occur in the enfeebled or those exposed to great hardships.

Variations due to age, pregnancy and other causes.—Typhoid fever is rare in infancy, but becomes more frequent in childhood, and then, generally, the symptoms are mild, the pyrexia of short duration and sometimes of a markedly intermittent or remittent type. Such complications as perforation or hæmorrhage are rare.

In the aged, particularly in those over sixty, typhoid tends to run an unfavourable course, hypostatic pneumonia and circulatory failure being common.

Abortion or premature delivery takes place in from 50 to 70 per cent. of pregnant women who contract typhoid. The fœtus is usually dead or, if born alive, usually succumbs to an acute typhoid septicæmia. The prognosis as regards the mother is not especially influenced.

In malarial patients the onset of typhoid may be sudden, with a typical rigor; but the severe symptoms proper to typhoid develop later. On the other hand, subtertian malaria may closely simulate typhoid in its commencement.

Chronic alcoholism exerts a very unfavourable influence. Pre-existing pulmonary tuberculosis is apt to advance rapidly during convalescence from the fever. In diabetes typhoid often runs a mild course.

Special Symptoms and Complications.—*Digestive system.*—Suppurative parotitis is attributed to ascending duct infection, and occasionally leads to cellulitis of the surrounding tissues. Due attention to the cleansing of the mouth goes far to prevent it. Ulcers sometimes appear on the pillars of the fauces and the pharyngeal wall (Duguet's ulcerations). Diarrhœa, although common, is not a constant feature, some patients being constipated throughout the disease. The severity of the diarrhœa does not depend on the extent of the intestinal ulceration, and it often disappears after a few days' hospital treatment.

Intestinal hæmorrhage occurs in about 7 per cent. of all cases, and is serious. It is most common at the time when the sloughs are separating, *i.e.* at the end of the second or beginning of the third week. The hæmorrhage may be slight, but more often is profuse. The evacuated blood is bright red in colour, unless it has been retained in the bowel. The signs of a severe hæmorrhage are a sharp fall in the temperature, a sensation of faintness, increased frequency of the pulse and, it may be, a transient rise in blood pressure with disappearance of dicrotism. The spleen may shrink rapidly. Sometimes the hæmorrhage is fatal before any blood is voided. There is a hæmorrhagic form of typhoid fever in which melæna may be an early sign, and is associated with petechiæ in the skin and hæmaturia.

Perforation of the bowel is responsible for one out of every 3 or 4 deaths. It is commonest towards the end of the third week, and is especially frequent in cases characterised by severe diarrhœa or by meteorism. Its onset may be preceded by intestinal hæmorrhage. The perforation generally lies within the last 12 inches of the ileum, where the ulceration is most severe and also most advanced; but perforation of the colon or the appendix may occur. Shivering, with the onset of sharp pain in the right iliac fossa, is usually the first sign. Localised tenderness, localised muscular rigidity and local immobility of the abdominal wall accompany the pain. The temperature may show a sudden drop to subnormal followed by a rise; but sometimes no variation is detected. Both pulse and respiration rates are usually increased, and the former should be watched carefully in all doubtful cases. Obliteration of the liver dullness may occur; this sign is especially valuable when occurring in a rigid and retracted belly. Another sign of some importance is the onset of irritability of the bladder with frequency of micturition. More reliance should be based on the local than on the general symptoms in making the diagnosis. After the first shock the patient may react and show deceptive signs of improvement, but before many hours the signs of spreading peritonitis will assert themselves. Unless dealt with surgically with the utmost promptness perforation is almost invariably fatal. A polynuclear leucocytosis generally accompanies perforation, but is inconstant and not of great diagnostic value.

Other causes of abdominal pain in typhoid fever are acute cholecystitis or perforation of the gall-bladder, suppurative cholangitis, portal pyæmia, suppurating mesenteric glands, appendicitis and splenic infarction, but none of these are common. Thrombosis of the iliac veins may also cause abdominal pain and tenderness, but a clue to this condition may often be found by examining the veins of the lower limbs and by looking for slight œdema of the leg or foot.

Respiratory system.—A mild bronchitis is present in most cases. In severe infections, and particularly in the later stages, hypostatic congestion of the

lung bases occurs. Lobar pneumonia is a complication which may supervene in the third or fourth weeks of the disease. Although typhoid bacilli may occur in the sputum, and be found in the lung, pneumococci are also present. Without careful physical examination the condition may be overlooked, as cough is often slight and rusty sputa absent. Embolic and pyæmic processes in the lungs during typhoid may give rise to abscess, gangrene and pneumothorax. Intra-pulmonary thrombosis, with infarction, is a very rare event.

Ulceration of the larynx is not infrequent in severe cases. It may be latent or give rise to huskiness of the voice, stridor, and toneless cough. There may be pain on deglutition and laryngeal tenderness. The slighter symptoms may abate, but sometimes the process terminates in necrosis of cartilage and œdema or stenosis of the larynx.

Blood and circulatory system.—A slight initial polynuclear leucocytosis is sometimes seen in the first week of infection. Later there is generally a marked anæmia associated with leucopenia, and a relative increase in the lymphocytes and large mononuclear cells. At the same time the eosinophils disappear, to reappear with convalescence. The appearance of a polynuclear leucocytosis indicates the onset of some inflammatory complications. An extreme degree of secondary anæmia usually persists during convalescence. A decided tendency to myocardial weakness is an important feature of the disease, and is indicated by a short and sharp first sound, feeble impulse and perhaps some increase in the area of cardiac dullness with the appearance of systolic cardiac murmurs. The blood pressure falls. In some cases the pulse becomes intermittent, irregular or alternating. During convalescence the pulse may remain rapid or become preternaturally slow. Sudden death during typhoid is usually to be attributed to the cardiac condition. Sometimes thrombosis of the cavities of the heart or of the pulmonary artery occurs. Endocarditis and pericarditis are rare events.

Femoral thrombosis is very apt to appear during early convalescence. It is usually left-sided, and sometimes appears to commence lower down in the veins of the popliteal space or calf or in the internal saphenous trunk. The complication is generally attributed to staphylococcal infection. The symptoms are pain and tenderness at the site of the thrombosis, fever and swelling of the limb, usually moderate in degree. The affected vein may often be felt as a rounded cord. In a few weeks the thrombus is absorbed, and the circulation re-established, but sometimes permanent obstruction and œdema result. The clot, if dislodged, may cause pulmonary embolism.

Arteritis, leading to occlusion, is an uncommon complication. The vessels affected are those of the lower limbs, sometimes those of the upper extremities, neck or brain.

Urinary system.—Febrile albuminuria is often present, but is transitory. Typhoid bacilluria occurs in about one-third of the cases, the urine presenting a slightly turbid, opalescent appearance; but a similar appearance may be due to the colon bacillus. Symptoms of pyelitis or of pyelo-nephritis may supervene. Urinary carriers continue to discharge typhoid bacilli for long periods. Acute nephritis is uncommon, but may occur either at the commencement or height of the disease. Retention of the urine may supervene during typhoid, but suppression is rare. During the fever the excretion of urea and of uric acid is increased, but the chlorides are diminished. Polyuria occurs at the onset of convalescence, and is of good omen.

Generative system.—Orchitis and, more rarely, prostatitis have been observed. In females acute inflammatory conditions of the vulva and also mastitis may occur.

Nervous system.—Meningeal symptoms at the onset have already been mentioned. Delirium is often present in some degree, and is usually of a quiet type. Drinkers may develop delirium tremens. Convulsions are rare. They may occur at the onset, or when occurring later may be due to cerebral thrombosis, encephalitis, or meningitis. Multiple neuritis or neuritis of such nerves as the ulnar may supervene, in the latter case often due to pressure. Acute tenderness of the toes during convalescence is also attributed to neuritis. During the course of the fever hemiplegia or aphasia may supervene. Sometimes there are signs of sclerosis of the lateral columns of the cord, the knee-jerks being increased, and an extensor plantar reflex present.

Mental disturbance is occasionally a sequel, taking the form of mania, melancholia or dementia. For many months after a severe attack the patient may remain in a fatuous condition but ultimately recover.

As regards the special senses, temporary deafness is often noticeable during the fever, and sometimes suppurative otitis occurs. Double optic neuritis is a rare complication and may lead to blindness.

Oseous and muscular systems.—During convalescence localised periostitis of the tibia, sometimes of the femur, ribs or other bones may appear. It may terminate in suppuration with limited necrosis. The inflammation is chronic and relapsing. Typhoid bacilli may persist in the discharge for long periods. A painful inflammatory affection of the ligaments and vertebral periosteum is the basis of the "typhoid spine." The lumbar and sacral regions are chiefly involved, with stiffness and pain on movement. The condition is chronic, but the ultimate outlook is said to be good. Arthritis of large joints is a rare occurrence; it may lead to dislocation of the hip.

Rupture of the rectus abdominis, sometimes of the adductors or other muscles, may take place. It is attributed to myositis and is accompanied by local hæmorrhage. The resulting fluctuating and discoloured swelling may clear up or go on to suppuration.

Cutaneous system.—Abscesses and boils may prove troublesome, particularly in children. Lineæ atrophicæ may form in the skin of the abdomen and thighs. In severe cases pressure sores may appear on the sacrum, the heels or other pressure points. These bed sores are a source of danger from septicæmia or pyæmia.

Diagnosis.—It is unnecessary to recapitulate all the symptoms already described as characteristic. Of the symptoms of onset, headache, slight epistaxis, disturbed sleep, a mild degree of bronchitis, abdominal uneasiness and some disturbance of the action of the bowels are very suggestive. Gradual daily increase in the pyrexia and its maintenance after the lapse of a week at a steady level of 103° or 104° F., with slight morning remissions, is important. Relative slowness of the pulse and the presence of dicrotism are additional diagnostic points. The dry furred tongue, slightly tumid abdomen, moderately enlarged spleen and the appearance of rose spots are confirmatory.

SPECIAL DIAGNOSTIC METHODS.—1. *Blood culture.*—This is particularly valuable in the first week before the agglutinative reaction has appeared or the rose spots are evident, but is also applicable during the second and third weeks and in relapse. Ten to 20 c.c. of blood drawn aseptically from a vein

at the bend of the elbow are allowed to run directly into plenty of broth or peptone solution or, better, into a medium which contains filtered bile or bile salts.

2. Cultures from the stools.—Owing to the presence of other intestinal bacteria this is not always an easy process, but by improved methods bacilli have occasionally been found during the incubation stage and in over 50 per cent. of the cases examined in the first week, a percentage increased to 70 or 80 in the third week. For methods, works on bacteriology should be consulted. Stool culture is also of value for the detection of intestinal carriers, and for determining whether a convalescent is fit to mix with other members of the community. The discharge of bacilli often being intermittent, more than one examination is necessary.

3. Cultures from the urine.—The typhoid bacillus hardly ever appears in the urine before the tenth day, and as a rule not before the fifteenth. The infected urine is generally opalescent and slightly albuminous. Cultures are made without difficulty and are useful not only for diagnosis but also for the detection of urinary carriers.

4. Agglutination tests.—Towards the end of the first week of the disease the blood serum becomes capable of agglutinating the typhoid bacillus. This power usually reaches its maximum about the eighteenth or twenty-first day. Blood is obtained from the lobe of the ear or elsewhere, received into a small glass tube and sealed. The serum which separates is mixed in various dilutions with a young (18 to 24 hours) broth or agar culture of the typhoid bacillus and a hanging-drop preparation made. Controls are indispensable. Agglutination of 1 in 50 with a time limit of one hour is usually taken as the positive standard. The bacilli first lose their motility and then aggregate into small clumps. The macroscopic method of applying the test allows the bacilli to sediment in flakes at the bottom of small tubes; Dreyer's method in which standardised dead cultures are used is the best; it is quantitative.

Normal blood serum does not show an agglutinating power greater than 1 in 10 or 1 in 20. The test is complicated by the development of co-agglutinins in other infections of the typhoid group. For instance, the serum of a patient infected with a paratyphoid bacillus may exert some agglutinative power on the typhoid bacillus. In such cases agglutination should be tested at short intervals and its degree noted in the case of both organisms, but more exact information is obtained by isolation of the infecting organism by blood culture. After anti-typhoid vaccination agglutinative power is developed in varying degree and persists for months or it may be for some years. In a person already inoculated against typhoid, agglutination is only important as evidence of infection if it be obtained in a dilution of at least 1 in 100.

5. The atropine test of Marris.—In typhoid and paratyphoid fevers atropine has but little power of accelerating the pulse. The patient lying quietly, the normal pulse rate is ascertained, being taken every minute until steady; about 10 minutes is required. A hypodermic injection of $\frac{1}{80}$ grain of atropine is then given. After 25 minutes, to allow time for the full effect of the drug, the pulse rate is again taken and recorded minute by minute until the temporary acceleration has ceased—15 to 20 minutes may be needed. If the pulse rise more than 20 beats, typhoid or paratyphoid is unlikely, but

if the rise does not exceed 10 beats the infection is probable. The reaction is most constantly observed in the second week. When the pulse is fast, the test is not so reliable, nor is it constant in those over 50 years of age.

6. *The Diazo reaction.*—A saturated solution of sulphanilic acid in 1 in 20 hydrochloric acid and a fresh half per cent. solution of sodium nitrite are required. Equal quantities of urine and sulphanilic solution are mixed in a test tube and a couple of drops of the nitrite added. By shaking, a froth is induced and ammonia is allowed to trickle down the side of the tube. If the froth become rose pink and the liquid turn crimson, the test is positive. The reaction may sometimes be obtained as early as the fourth day, and persists during the height of the fever. Unfortunately it also occurs in measles, typhus fever, scarlet fever, pneumonia, tuberculosis and erysipelas.

DIFFERENTIAL DIAGNOSIS.—Prominence of respiratory symptoms in typhoid fever may lead to the infection being overlooked. Conversely a deep-seated or apical *pneumonia*, or, in children, broncho-pneumonia with intestinal disturbance, may simulate typhoid. Careful and repeated physical examination, blood culture and agglutinative reactions will lead to a correct diagnosis. When typhoid is prevalent, caution is necessary in arriving at a diagnosis of primary bronchitis, pneumonia or broncho-pneumonia.

Differentiation from *acute miliary tuberculosis*, from *tuberculous meningitis* and from *tuberculous peritonitis* is often difficult. Acute miliary tuberculosis may simulate typhoid in its insidious onset with malaise and headache, its rising temperature with morning remissions, its comparatively slow pulse, its bronchitis, and perhaps some enlargement of the spleen. But the temperature tends to be more irregular, sweats are present, the *dyspnoea* and *cyanosis* are suggestive, and *signs of pleurisy* may develop. There are no rose spots, and agglutinative tests and blood culture give negative results (tubercle bacilli are rarely found). Tuberculous meningitis is differentiated by such symptoms as vomiting, convulsions, the persistence of headache after the first week, or when delirium is established. A pulse hardly raised above the normal rate, stiffness and retraction of the neck, the presence of Kernig's sign and of retraction of the abdomen or the onset of ocular paralysis are very significant. The irritability and curled-up decubitus of meningitis contrast with the apathy and dorsal decubitus of typhoid. Lumbar puncture will clinch the diagnosis; in tuberculous meningitis lymphocytes are in excess in the cerebro-spinal fluid, and sometimes tubercle bacilli may be demonstrated. The question of meningo-typhoid has already been discussed. Tuberculous peritonitis may resemble mild typhoid fever. The presence of tuberculous masses in the abdomen or the development of peritoneal or pleural effusions is significant. In cases with indefinite symptoms and no signs of tubercle elsewhere, negative blood culture and agglutination tests afford assistance.

Suppurative and pyæmic conditions may give rise to fever and constitutional disturbance bearing some resemblance to typhoid. Among these must be mentioned appendicitis and the intraperitoneal abscesses which may result from it, perinephric abscess, cholecystitis, pelvic, or puerperal infections, infective endocarditis and deep-seated osteomyelitis. The diagnosis is made by careful attention to the history of onset and course, thorough and complete physical examination, and the frequent presence of a pronounced polymuclear

leucocytosis. Profuse sweats and rigors are more likely to occur, and the temperature chart is more irregular. The blood serum fails to agglutinate typhoid bacilli, nor can they be obtained by blood culture, which may, however, reveal the presence of other organisms.

Typhoid fever in its early stages is often mistaken for *influenza*, but in the latter the onset is generally sudden and the early symptoms are more severe. The temperature reaches its maximum much sooner. The pains in the limbs and the backache are more intense, and the headache, which has a neuralgic character, is frequently supra-orbital. Catarrh of the conjunctivæ and nose may be present, and perspirations are often marked. Defervescence usually takes place within a few days. A sharp drop of temperature after 2 or 3 days with a sudden rebound 12 or 24 hours later is very characteristic. If a supposed influenzal fever persist without definite cause, typhoid should be suspected.

A mild case of *typhus* may bear a close resemblance to typhoid, and severe typhoid with grave toxæmia, stupor and a profuse eruption may be mistaken for typhus. Points in favour of the disease being typhoid are a slower onset, the later appearance of the eruption, which is never petechial, and the presence of bowel symptoms. Typhus, on the other hand, has a sudden onset with high fever which sooner attains its maximum and does not show morning remissions. Conjunctival injection, contracted pupils and a drunken expression are the rule. The rash appears on the fourth day, becomes petechial and is accompanied by subcuticular mottling. Prostration is marked and there is a greater tendency to delirium and stupor. Crisis occurs about the fourteenth day. The Weil-Felix reaction is present, but agglutination tests for typhoid are negative.

Undulant (Malta or Mediterranean) fever is distinguished from typhoid by its relapsing character, the prominence of arthritic pains and joint swellings, and the fact that the blood agglutinates the *Micrococcus melitensis*, which organism can also be recovered by blood culture. Closely allied to this is the fever produced by *B. abortus* of cows.

When *malarial fever* assumes the continuous type, which is likely to occur with the malignant infections, the diagnosis turns on known exposure to malaria, sudden onset, the detection of malarial parasites in the blood and the reaction to quinine. Malaria and typhoid fever, however, may coexist.

The fever of *secondary syphilis* is sometimes sufficiently severe to suggest typhoid, especially when accompanied by headache, malaise and muscular pains. Diagnosis depends on the history or detection of a primary lesion, the possible presence of a secondary roseolar eruption and on laboratory tests.

Amongst other diseases at times confounded with typhoid must be mentioned glanders, trichinosis, fever due to *Ascaris lumbricoides*, scarlet fever in which pyrexia is prolonged, and especially other fevers of the enteric group, i.e. paratyphoid A, B or C.

Prognosis.—Taking all ages, the death-rate varies from 5 to 25 per cent. It is higher in some epidemics than in others. The average hospital death-rate in London is 17 per cent. or a little less. Age has a decided influence on the mortality, which is least in children under 10. after which there is a steady increase with advancing years. Infants are believed to stand the

infection very badly. Obesity, alcoholism, privation and fatigue are adverse factors. The influence of pregnancy has already been discussed. Indications of a grave attack are a pulse rate of 130 or 140, cyanosis with signs of myocardial weakness and hypostatic congestion of the lungs; marked delirium and subsultus or actual coma, persistent diarrhoea, tympanites, incontinence of urine and fæces. A temperature of 103° or 104° F. is not necessarily unfavourable unless it is sustained beyond the usual period or accompanied by signs of heart failure. Delayed appearance of the agglutinative reaction in some instances indicates a severe attack.

Of the complications, perforation is the most grave. Without operation it is almost invariably fatal. With operation the recovery rate is difficult to fix—some surgeons claim success in over 30 per cent., but the intervention must be immediate. The average recovery rate is very much lower. Hæmorrhage from the bowel is undoubtedly serious, especially if repeated. Such complications as meningitis, lobar pneumonia and acute nephritis are dangerous but fortunately not very common.

Sudden death sometimes occurs, either at the height of the fever or in convalescence. It may be caused by intense toxæmia and myocardial failure, cardiac or pulmonary thrombosis or pulmonary embolism. Rarely no definite cause can be assigned.

Treatment.—*Prophylaxis.*—Patients suffering from typhoid fever should be isolated. Since the bacilli are found in the fæces, the urine, the pus from abscesses, the vomit and the sputa, adequate disinfection of these is necessary. Blood discharged from the nose or bowel should also be looked upon as infectious. Equally essential is the disinfection of the bedclothes and personal linen of the patient, the feeding utensils, thermometer, bed-pan, urinal, spittoon and enema syringe. The stools and urine should be mixed with an excess of some such disinfectant as carbolic acid or corrosive sublimate, and allowed to stand for several hours before being thrown down a drain. The sputa should be received in small cloths which can be burned, or expectorated into a disinfectant solution. The clothing and bedclothes of the patient should be soaked in a 1 in 20 solution of carbolic acid before being sent to a laundry.

Nurses in attendance should submit to prophylactic inoculation and take special precautions for their own safety. Overalls will obviate soiling of the clothes. If the bath treatment be adopted, rubber aprons which can be carbolised are advisable. Rubber gloves may be worn when giving enemas or touching bed-pans and urinals, but always it should be realised that typhoid acquired by contact is a disease conveyed by unclean hands, and the danger may be obviated by washing with plenty of soap and water after touching the patient or anything which has been in contact with him. Mere splashing the fingers in a bowl of disinfectant is useless. The nurse will see that everything leaving the patient or used by him is sterilised at once. Feeding utensils should be boiled after use.

In most cases the bacilli rapidly disappear from the excreta in convalescence, only persisting for a few weeks, but bacteriological examination several times repeated affords the only reasonable proof of safety. About 5 per cent. of those attacked become carriers. In most the carrier state is temporary and an arbitrary period of 3 months is allowed before the condition is deemed chronic. Intestinal carriers are more common than urinary

carriers. In both the discharge of bacilli may be intermittent. Symptoms referable to the gall-bladder and periodic bowel disturbance occur in some intestinal carriers, and urinary carriers in like manner may suffer from kidney trouble or cystitis.

Carriers are often responsible for the endemic persistence of typhoid in certain houses or localities and are particularly dangerous when employed in the preparation of food or in dairy work. They should be prohibited from following these occupations. Since they may spread infection by contaminating their own hands during defæcation or micturition they should be scrupulous in washing after attending to the calls of nature and have towels reserved for their own use. Their soiled bed and body linen must be disinfected. Medical treatment by the use of intestinal and urinary antiseptics, surgical by excision of the gall-bladder, and treatment by autogenous vaccines have up to now alike failed to solve the problem of the chronic carrier. Preventive inoculation of contacts is the most effectual method of limiting their danger and is adopted in special circumstances. Some carriers give no history of an attack of typhoid and may themselves ultimately develop an attack of the fever or suffer from typhoid septicæmia after operations on the gall-bladder or kidney.

A pure water supply and an efficient system of drainage are important factors in the prevention of typhoid epidemics. When the disease is prevalent, drinking water and milk should always be boiled, and travellers in localities where it is endemic should adopt similar precautions. Uncooked vegetables and, in particular, radishes, salads, cress, tomatoes, cucumbers, strawberries and other fruits are liable to contamination. Oysters and other shell-fish should be avoided unless their source is known to be above suspicion. The disease has been contracted by bathing in sewage-contaminated water.

Prophylactic vaccination.—Immunity can be artificially induced by vaccination with typhoid vaccine. There are several methods of preparation of vaccine, one of which is to heat a 48-hour broth culture to 58° C., and complete the sterilisation by the addition of 0·5 per cent. lysol. Exposure to higher temperatures diminishes the potency of the vaccine. The number of bacteria in the first dose is 500 million, a double dose is given 10 days later and repeated 10 days later still. The injection is made subcutaneously and preferably not after a heavy meal or exposure to fatigue. A mild local reaction and sometimes constitutional symptoms may occur a few hours after injection, hence the patient should rest. If the patient be already infected the reaction may be more severe. The duration of the immunity conferred is said to average 1 to 2 years and to be proportional to the dosage employed. It is believed that an individual inoculated at the beginning or even in the middle of the incubation period of typhoid has a good chance of escaping the fever. For army purposes, triple or quadruple vaccines of the organisms of typhoid and paratyphoid are largely employed.

General.—In the absence of efficient sera or vaccines there is at present no specific. Skilful nursing and a suitable diet are of the first importance. The room should be kept at a temperature of 60° F., and the bed narrow and of a convenient height. A hair mattress should be covered with two folds of blanket and a waterproof sheet over which is placed a sheet, and under the hips a draw sheet. A water-bed is unnecessary. A sheet and

coverlet with a blanket over the feet are usually sufficient covering. Night and morning the patient should be sponged with tepid water, and parts exposed to pressure should be rubbed with methylated spirit and dusting-powder applied. Rucking of bedclothes should be avoided. The urinal and bed-pan should be used in the recumbent position, and the buttocks sponged, dried and powdered after each motion. The mouth should be cleansed after each meal with boroglyceride solution or a weak alkaline carbolic wash. From time to time it may be advisable to move the patient from the dorsal position to avoid hypostatic congestion of the lung bases. Stools and urine should always be reserved for inspection by the medical attendant, who should never neglect daily examination of the abdomen, and should also satisfy himself that the patient, especially if restless, has not retention of urine. The temperature and pulse should be charted 4-hourly, and more frequently should complications be suspected.

Milk is the most suitable diet for patients in the acute stages. It should be given in measured quantities at 2- or 3-hourly intervals, the patient not being disturbed at night should he be sleeping. Three pints a day is, despite theoretical considerations, quite sufficient. The milk may be diluted with barley water or lime water, and plenty of plain cold water allowed between the feeds. Aerated waters are best avoided, but tea may be allowed or lemonade made with dilute hydrochloric acid and syrup of lemons. Should intestinal discomfort occur or curds appear in the motions the milk may be citrated or whey substituted. Beef-tea and meat extracts, being laxatives, are to be avoided in diarrhoea or hæmorrhage. A pint of beef-tea is ample. Carbohydrate can be added to the diet in the form of cane sugar or maltine, or an ounce of glucose may be allowed in warm water during the day. A form of soluble casein, such as plasmon, may be used to fortify the milk.

When the temperature has been normal for 3 days, cautious additions may be made, beginning with thin custard or grated bread-crumbs and milk, and then adding a small quantity of boiled or steamed fish, thin bread and butter, and so on.

A more liberal diet during the acute stage is advocated by some, i.e. milk puddings, custards, eggs, vegetable or meat soups strained and thickened with arrowroot or flour, finely minced lean meat, bread crumbs and mashed potato. Such feeding is said actually to diminish the tendency to perforation and hæmorrhage, and to hasten convalescence. It is not suitable in severe attacks or for patients with profound toxæmia and deficient digestive secretions. Alcohol is rarely necessary, but it is unwise suddenly to deprive alcoholic patients of all stimulants, and a moderate allowance of brandy or good whisky is by many held to be beneficial in cases of severe prostration with weak pulse, hypostatic congestion of the lungs, delirium and tremor. There is no advantage in giving more than 4 or 6 ounces in 24 hours, and it should be given in small quantities diluted. In children it is quite unnecessary. The use of chewing-gum will encourage flow of saliva and help to keep the mouth in a healthy state.

Of special methods of treatment, three require consideration: the antipyretic, the antiseptic, and the eliminative.

The antipyretic method assumes that pyrexia itself is harmful. The cold bath is most efficient, but has never gained a great vogue in England. When-

ever the temperature rises above $102^{\circ}3$ F., the patient is lifted into a bath at 65° F. and immersed for 15 minutes, shivering being disregarded. The limbs and trunk are rubbed whilst in the bath. The patient is then removed, laid on a blanket, dried and lightly covered. A little alcohol is given immediately before or after the bath. Immersion is repeated every 3 hours unless the temperature remains below the point mentioned. Contra-indications are hæmorrhage from the bowel, severe abdominal pain, venous thrombosis or great prostration. The method needs good attendants, and can hardly be applied in private, but it is said to reduce the case mortality by a half or even two-thirds. In place of the bath, tepid, cold or ice sponging may be adopted when the temperature is high or the cold pack used, especially when nervous symptoms are pronounced. The ice cradle is another useful means of refrigeration; the patient is covered with a sheet, and a cradle, in which small bags of ice are suspended, is placed over the body, the whole being covered with a thin blanket. The cradle may remain in position indefinitely, the effect on the temperature being carefully watched.

Of antipyretic drugs, the most important are quinine, phenazone, acetanilide, phenacetin and acetyl-salicylic acid. They are recommended for occasional use only.

The antiseptic mode of treatment was adopted when it was unknown that typhoid was a true septicæmia and not a local bowel infection. Antiseptics, however, by diminishing fermentation, may check diarrhœa and prevent tympanites. Many have been used, but those which have the best reputation are sulphurous acid, oil of turpentine, and a mixture of quinine and nascent chlorine as advocated by Burney Yeo. Dr. Foord Caiger strongly recommends the use of oil of cinnamon throughout the disease, the dose being $2\frac{1}{2}$ to 5 minims every 2 hours in an emulsion or in cachets.

Eliminative treatment by the administration of purgatives is now rarely adopted, but during the first week of the disease the administration of calomel in 3-grain doses, followed some 7 hours later by irrigation of the colon with warm water, may be beneficial.

Constipation should be met by a simple enema every second day. *Diarrhœa*, if accompanied by curds, calls for reduction of the milk. A starch and opium enema is useful, or 10 grains of Dover's powder by the mouth. In hæmorrhage from the bowel the most absolute rest is essential. Food should be reduced to a minimum or withheld for 12 or 24 hours. No stimulants or beef-tea are permissible. Ten minims of laudanum or a hypodermic injection of $\frac{1}{4}$ grain of morphine should be given, and an ice bag applied to the right iliac region. A watch should be kept for signs of perforation. Intravenous saline infusion, or, better, transfusion of blood, may be necessary in severe cases. The injection of a solution containing 1 grain of chloride of calcium in 10 minims of water into the gluteal region is worth a trial. *Perforation of the bowel* calls for immediate operation, no delay is permissible. *Meteorism* may be controlled by reducing the diet, administering enemata of hot water, and inserting the rectal tube. A turpentine stupe or ice poultice may be applied to the abdomen. Turpentine by the mouth or by enema, and oil of cinnamon are useful. For *delirium*, *sleeplessness* and *headache*, the reduction of temperature by sponging or cradling and the administration of 10 or 15 grains of Dover's powder should be tried. Sometimes trional or chloralamide is effectual. *Circulatory failure* is combated by strychnine hypodermically

or by injection of camphor dissolved in oil or ether. *Strophanthus* and *digitalis* are of doubtful value. Alcohol is strongly advocated by some physicians. Adrenalin also is of use. The supervention of *femoral thrombosis* calls for strict immobility of the limb. The intravenous injection of 5 or 10 ounces of a sterile 0·5 per cent. sodium citrate solution relieves the pain, and is said to arrest the progress of the thrombosis. *Bacilluria* and *cystitis* are treated by hexamine in 10-grain doses, 3 or 4 times a day. Of the suppurative and septic complications, *periostitis* may be influenced by rest, local applications and typhoid vaccine, but suppuration calls for surgical intervention. *Parotitis* usually comes to incision. *Cholecystitis* may subside, but if it persists operation becomes necessary. Crops of *boils* call for local treatment, and the appropriate vaccine should the organism be identified. The intramuscular injection of colloidal manganese is useful in such conditions. The infectivity of the purulent discharge should be remembered.

PARATYPHOID FEVER

Ætiology.—Paratyphoid fevers are, like true typhoid, ubiquitous in their distribution, but the prevailing type is different in different countries and in different climates. Paratyphoid A is prevalent in India and other tropical countries. The experience of the Great War led to the suspicion that it may have been endemic, although unrecognised, in the Mediterranean area, and perhaps also in France, Flanders and Germany. In European countries, however, paratyphoid B is the more common type. Paratyphoid C occurs in the Balkans, and possibly there are also other varieties. *Bacillus paratyphosus* A and *B. paratyphosus* B are organisms which under natural conditions only attack man. *B. paratyphosus* C is by some considered identical with *B. suispestifer*, the hog-cholera bacillus.

The greatest incidence of paratyphoid is in the summer and early autumn, but it may occur at other seasons of the year. It is more prevalent in hot countries, and all ages are susceptible. In ordinary circumstances it affects both sexes equally.

The primary source is a patient suffering from an attack, or a carrier of the bacillus. Contagion, as with typhoid, may be direct or indirect through food, drinking water, fomites, etc. The fact that infected meat, particularly pork, may induce symptoms resembling paratyphoid fever should be borne in mind.

Symptoms.—The *clinical manifestations* of paratyphoid infections are practically indistinguishable from those of typhoid fever, but the belief is generally held that paratyphoid differs from typhoid in its milder character and shorter course. This is on the whole correct, but marked exceptions occur. Occasionally paratyphoid infection is said to produce an illness which resembles acute irritant poisoning, or so-called ptomaine poisoning. But such infections are more likely to be caused by *B. aertrycke*, which in its agglutination reactions closely resembles *B. paratyphosus* B. In true paratyphoid the subsequent course is clinically unmistakable.

The septicæmic stage of paratyphoid is of short duration, rarely lasting more than a week, hence blood cultures for diagnostic purposes should be

taken as soon after the third day as possible. The distribution of the infecting organisms in the body is similar to that of typhoid, and they are discharged in the feces, the urine, the bronchial secretions, and the pus of suppurating foci.

The *incubation* period varies from 9 to 15 days, but may be shorter.

The *onset* is more often insidious than sudden, the invasive symptoms resembling those of typhoid, but a sudden onset is believed to be more common than in the latter disease. Shivering and vomiting are not infrequent symptoms of such invasion. Sometimes gastro-intestinal symptoms are for a time very prominent. As with typhoid; appendicitis, meningitis, or pneumonia may at first be simulated. Sometimes the disease declares itself after several weeks of premonitory diarrhoea, or it may closely resemble dysentery.

The fever attains its maximum sooner than in typhoid, and may be at its height by the third or fourth day, by which time, if not before, the patient will have taken to bed with symptoms suggesting typhoid of a week's duration. The head aches, the patient is apathetic, and the spleen is generally palpable and sometimes tender. The liver may be slightly enlarged, and the gall-bladder tender if cholecystitis be present. The abdomen is generally somewhat tumid, but marked distension is uncommon. Diarrhoea may occur at the onset, but constipation is more common. Sweating is often a more pronounced feature than in typhoid. Rose spots are present in unusual profusion in some cases. They usually appear towards the end of the first week. In size, too, they often appear larger than those seen in ordinary typhoid infection, and the rash may continue to come out after the temperature has fallen. Pulmonary complications are mild, but bronchitis and broncho-pneumonia may occur. In the more severe cases, the heart may show signs of dilatation. It is exceptional for the patient to pass into the "typhoid state." The fever has a shorter duration than in typhoid. Within a fortnight, sometimes sooner, it has generally fallen by rapid lysis to normal. The slow pulse and low blood pressure of typhoid are also seen in the paratyphoid variety. Relapse is said to be just as frequent.

Complications.—Intestinal hemorrhage is much less common and less severe than in true typhoid. Perforation is rare. Thrombosis of the femoral or saphenous veins or their radicles is not uncommon, and broncho-pneumonia or pleural effusions may occur. Cholecystitis and catarrhal jaundice may be due to paratyphoid organisms, as also bacilluria, cystitis, pyelitis and even pyelonephritis. Orchitis is an occasional complication, and is believed to spread from the urinary tract. Other complications, which have mostly been observed in army practice, are laryngeal ulceration, parotitis, periostitis, sometimes suppurative, peritonitis without perforation of the bowel, and pylephlebitis, attributed to lesions of the appendix.

Diagnosis.—For the differentiation of paratyphoid from typhoid infections and of the varieties of paratyphoid from each other, recourse must be had to bacteriological methods, i.e. to blood culture, agglutinative reactions and cultures from the stools and from the urine. Of these methods, blood culture in the early stages is the most satisfactory. If agglutination occur in high dilutions with one of the paratyphoid organisms and little or not at all with the others and the organism of typhoid, the nature of the infection is evident; but in other cases the examination has to be repeated at short intervals and the results compared. A rising agglutination for one organism indicates

it as the causal agent. Some infections with paratyphoid C fail to produce agglutinins in the patient's serum.

Prognosis.—The prognosis in paratyphoid infections is better than in those due to the *B. typhosus*, the proportion of severe infections being much smaller. The causes of death are chiefly hæmorrhage, perforation, lung inflammations and toxæmia.

As regards differential diagnosis, prophylaxis and treatment, what has already been said with regard to typhoid applies.

CHARLES R. BOX.

BOTULISM (see p. 395).

BACILLUS COLI INFECTIONS

Amongst the many additions to sound medical knowledge which we owe to the rapid development of the science of bacteriology, none is more striking, or fraught with more practical results in the treatment of disease, than the information which has led to our present-day conception of the nature and extent of *Bacillus coli* infections. Our knowledge of the pathogenic effects of this group of micro-organisms has entirely remodelled our views in regard to many disease-processes which were recognised, but were formerly ill-understood. And, in addition, disease-processes which were formerly quite unrecognised have been brought to light.

The beginnings of such knowledge date from the isolation of the typhoid bacillus in 1880, and the isolation, five years later, of the *B. coli communis* from the healthy intestine. Continued and extended observations, made possible by the introduction of newer differential bacteriological methods, have resulted in the recognition of a large and important group of bacilli, called the *B. coli group*, including members which differ as widely in pathogenicity as these two originally described bacteria, but also including the organisms of bacillary dysentery, Gaertner's bacillus of food-poisoning, the paratyphoid organisms, and a number of variants of *B. coli* whose differentiation still proceeds. The group is as large and as complex as the streptococcus group in which, similarly, are recognised the virulent *S. pyogenes* at one extreme and the feebly pathogenic *S. faecalis* at the other.

We are still, however, a long way from getting a full conception of the rôle played by *B. coli* in disease. In many cases we are quite unable to decide whether the presence of the bacillus in a situation which it does not normally inhabit is the causative factor in a patient's illness. To assume that it is, without good evidence, may involve an important fallacy, and may lead to our overlooking another, and more responsible, factor. It is certain that *B. coli* may be found in some abnormal situations, as in the urinary bladder, in persons who enjoy good health. The microbe has become, as it were, saprophytic there. But such a state of things must at least be regarded as having potential pathogenic effects.

MODES OF INFECTION.—In health, *B. coli* are confined to the intestine. The modes of infection of parts of the body other than the bowel are at times very apparent, at others obscure. Of any particular tissue there are three

possible routes of infection: (1) The *direct* route, that is, by the immediate transference from the bowel to the infected area; (2) by the *lymphatics*; and (3) by the *blood stream*. In some infections, e.g. of the gall-bladder, pericolic tissues, pelvic cellular tissue, etc., the direct route is no doubt the one generally followed. Of the two indirect routes, however, some doubt exists as to the more likely one in certain cases, such as infection of the urinary tract especially; in some instances of this latter important condition, it is clear that invasion takes place again, directly, through the urethra. The cystitis which still occasionally follows the use of the catheter illustrates this; and the greater frequency of *B. coli* cystitis in little girls than in little boys has been adduced in favour of this route. In the acute pyelitis complicating or following typhoid fever, it is highly probable, though not certain, that infection proceeds via the blood stream to the kidney, and thus to the pelvis. But in those acute primary infections of the urinary tract, which are so common in both sexes, the mode of entry of the bacillus to the kidney pelvis is problematical.

SITES OF INFECTION.—The sites of infection by *B. coli* are very numerous. Mention will only be made here of those which form the basis of important disease-processes which demand recognition and treatment in practice.

1. The *bowel* itself may be the site of infection. This may take place (a) because the infecting strain of *B. coli* has absolute pathogenic qualities; or (b) because the virulence of one or more of the usually saprophytic strains is increased; or (c) because the resistance of the mucosa is lowered by chemical or physical changes or by infection by another pathogenic microbe. From one or more of these factors acute or chronic *enteritis*, *entero-colitis*, or *colitis* may ensue. Gaertner bacillus poisoning, the result of eating contaminated food, is an important instance of (a), and perhaps also of (a) combined with (c). Some cases of *cholera nostras* appear to be due to *B. coli* infection, and probably most sporadic cases of acute colitis. There is no great obscurity attaching to these infective processes. In a consideration of many cases of *chronic colitis*, however, the exact rôle of *B. coli* is very obscure indeed; and this, even when we exclude a large number of cases of bowel defect to which the name *colitis* should never be applied at all. It is probable that many of the patients said to be suffering from *intestinal intoxication* are in reality the subjects of subinfection by *B. coli*. But at present our criteria for judging accurately of such a condition are lacking. Mere qualitative bacteriological investigations of the *fæces* in such cases yield at most presumptive evidence, and quantitative investigations take us very little farther. We await some method of estimating tissue infection by the coliform group more constant than agglutination, which is rarely present in chronic cases, and is, therefore, of little use as a guide.

2. *Gall-bladder sepsis* is closely associated with *B. coli* infection. It is commonly held that sub-infection of the gall-bladder by this microbe is one of the important factors in the evolution of cholelithiasis. However this may be, it is certain that *B. coli* is the most frequent infecting agent in *cholecystitis*, both acute and chronic. The fact harmonises with the known frequency of gall-bladder infection during typhoid fever.

3. *Appendix inflammations*, *diverticulitis*, *pericolic suppuration* and local peritonitis complicating intestinal conditions, are all of them associated with *B. coli* infection, and in many instances with this alone.

4. The urinary tract is infected with great frequency, with how great frequency we are only now realising, as the result of systematic cultivation of the urine in doubtful cases of the condition, and in obscure cases of illness in which no such condition is at first suspected. It is important to note, however, that the mere presence of *B. coli* in the urine—it is assumed that catheter specimens only are being dealt with, or that, when this is not the case, there is good evidence that the bacilli actually come from the bladder—does not establish an actual urinary tract infection. *B. coli* in the urine may signify one of either of the following conditions: (a) The elimination of the bacilli from the body through the kidney, without infection either of this organ or of the urinary tract: this process is usually of brief duration, and may be intermittent. (b) The excretion of bacilli (with pus) from an infected kidney or from some focus of infection adjacent to the urinary tract (prostate, urethra, pericolic tissues). (c) True infection of the urinary tract (pyelitis, cystitis, pyelo-cystitis). (d) *Bacilluria*.

Concerning (a) and (b) no more need be said in this place, but (c) demands more consideration.

B. COLI INFECTION OF THE URINARY TRACT.—The cases met with may be conveniently described as falling into three groups.

(i.) *Acute cases*.—In the majority of these cases the infection appears to arise in the pelvis of the kidney; some are undoubtedly vesical in origin; in not a few it is uncertain where the infection begins. The disease is at times quite fulminating in its acuteness, being ushered in by rigors, high fever (103° to 105°), delirium and great drowsiness. More often the symptoms are abrupt and severe, but not alarming. There may be pain and tenderness in the loin, and one or other kidney may be tender under bimanual examination. But in more cases than not there is a striking absence of both physical signs and focal symptoms, so that, unless the existence of the disease is borne in mind, and the urine is examined carefully, the patient is thought to be suffering from “influenza.”

In those cases in which the bladder is, from the first, markedly affected, symptoms of *dysuria* are present—frequency, pain and strangury. Such symptoms draw attention, of course, to the nature of the process.

The urine shows a great range of variations in its features. There may be a fairly frank *hæmaturia*, a fact which is not so widely known as it should be: *B. coli* infection is the explanation of a large number of obscure cases of hæmaturia. The amount of pus is very variable—it may be very considerable, or it may be represented only by leucocytes seen on microscopic examination. In very severe cases portions of the bladder mucosa may be shed in the form of sloughs, but this is uncommon. Like the pus, the bacilli vary greatly in the degree to which they are present in the urine; in some cases they are so abundant as to constitute by far the greater part of the total sediment. The colour and amount of the urine depend upon the degree of pyrexia and the amount of fluid ingested. Constipation is the rule, the tongue is generally covered by a creamy fur, and anorexia is common. As in so many acute *B. coli* infections, the mental state tends to depression.

The disease is often a strikingly dramatic one in children; there is a maximum of febrile reaction with lassitude and even stupor, and a minimum of serious effect upon the vital organs. It is not very uncommon to see a temperature of 105° or 106° , with big intermissions; the child is very ill

during the pyrexial stage and comparatively well when the temperature falls.

The course of the disease varies much. Prompt recognition of its nature, leading to appropriate treatment, usually results in defervescence and the disappearance of pus and bacilli from the urine in 7 to 14 days. But some of the cases last many weeks; it is fair to say that this is not seldom due to failure to diagnose the condition, or to employ efficient measures of treatment.

Relapses are very common. Of *complications*, *prostatitis* is perhaps the one most often seen; *epididymitis* occurs less often, but is a very definite condition; *urethritis* may occur. It is interesting to record that *epididymitis* may be the first symptom of the disease.

(ii.) *Recurrent cases*.—A not uncommon type of case is that in which symptoms of acute or of subacute infection occur at intervals over a number of years, the condition of the patient and of the urine being natural between the attacks. Recurring hæmaturia, thought to be due to acute nephritis, to tuberculosis or to calculus, is sometimes due to this condition. The probable source of these re-infections in any individual case is the colon.

(iii.) *Chronic cases*.—These are either (a) the sequelæ to acute attacks that have never completely resolved; or (b) they arise insidiously; or (c) they follow instrumental procedures or operations upon the urinary tract; or (d) they complicate mechanical defects, such as stricture and enlarged prostate; or (e) they occur as secondary infections in cases of renal or vesical calculus or of tuberculosis.

The symptoms in these chronic cases vary greatly. In one group it is the general toxic state that is the main feature—a sallow complexion, loss of tone, a low blood pressure, colon dyspepsia, headache and backache. In another group the local symptoms predominate—increased frequency of micturition, which may be extremely trying, pain during or after the act, and referred pain and discomfort in the vesical zone. In a third group there is little or no interference with health, general or local; but a vivid realisation of the existence of the condition troubles the patient's mind, leading sometimes to a state of bladder neurasthenia.

The urine in chronic infections shows as much variety as do the symptoms. The characteristic “fishy” odour is rarely absent; the reaction is generally acid, the amount of pus present may be very little or may be considerable, but the degree to which the patient is troubled by no means corresponds to the degree of pyuria; mucus is in excess; bacilli are constant and, like the pus, are very variable in quantity. *Hæmaturia* is uncommon in chronic infections, but it is easily induced by instrumental investigation, as are also “flares-up” of the chronic state, with the production of rigors, high fever, severe malaise and relative anuria. For this reason, careful deliberation is called for in deciding whether or not the bladder should be explored in these cases; and, in regard to exploration of the pelvis of the kidney, extreme forbearance should be exercised.

BACILLURIA.—This term is properly applied to a urine which is loaded with bacilli, but in which there is no pus, or, at most, a few leucocytes seen on microscopic examination. It is a state of kidney elimination of bacilli rather than a condition of bacillary infection. It is usually of short duration. The appearance of the urine is characteristic; shimmering when agitated

and viewed by transmitted light. The smell already referred to as so typical of colon bacillus urinary infections is usually present here also.

OTHER SITES OF *B. COLI* INFECTION.

(i.) *The uterus and Fallopian tubes* are sometimes the site of infection, as in puerperal sepsis; but the infection is then usually a mixed one, with streptococci.

(ii.) Some situations quite remote from the bowel are now and again infected by *B. coli*—the *middle ear*, the *pleura*, the *bronchial tract*, *bones* and *joints*.

B. COLI SEPTICÆMIA, unless it occur as a terminal event, in which form it is not at all uncommon, is rare. When it does occur, however, it is by no means always fatal. *Infective endocarditis*, due to *B. coli*, is rarer still; the only cases coming under the writer's notice have been of the nature of a terminal infection.

Treatment.—The treatment of cases of *B. coli* infection may be considered under three heads—general, local, and specific measures.

1. *General measures.*—In all acute cases the patient is kept in bed, so as to ensure rest and warmth. Both of these are essential, and even in chronic cases it is of great importance to avoid cold and fatigue. As the *bowel* is the source of nearly all the infections, attention to it is paramount. It is quite impossible to say in how many seemingly unlikely cases the intestine, and especially the colon, will be found to give the clue to treatment, provided the possibility be borne in mind. Especially is this the case in acute and subacute cases. To correct constipation is not enough—constipation may not even be present—efforts must be made to change the bowel contents in such a way that they are no longer so good a nidus for growth of the bacillus. This is best attained by a *diet* which is *low in total protein content*; meat, eggs and raw milk are *excluded entirely*; *junket*, *wey*, *buttermilk* and *cream* being allowed. The following articles of food are also allowed: *macaroni*, *boiled rice*, *raw and cooked fruit*, *salads*, and *lightly cooked green vegetables*, *jams*, *marmalade*, *honey*, *cold fat bacon* and *ham*, and *chicken* and *white game* occasionally. *Wholemeal bread* and *oatmeal porridge* are recommended. On such a diet the consistency of the stools soon improves, and they lose their ill-digested appearance; as also mucus and sandy deposit, if these were present. They also become much less offensive to the smell. Plain drinks are encouraged—preferably between meals.

If the case be acute, with considerable pyrexia, the practitioner will generally consider milk the staple food indicated—it is the English doctor's sheet anchor in every acute febrile disturbance; but even in these cases it is often possible to demonstrate rapid progress so soon as the milk is disallowed.

The choice of aperients is of great importance. In acute cases, *calomel* is very useful combined with salines. In chronic cases, the most helpful form of laxative is of the agar-agar type (*regulin*, *cascagar*, *jubol*), supplemented if necessary by a compound aloin pill. *Bowel "antiseptics"* are worth trying, and, if tried, are worth persisting in. The writer gets the best results with a cachet containing *salol*, grs. x, *hydrarg. cum. cret.*, gr. $\frac{1}{2}$, given with water, between meals, twice or three times daily. *Izal* oil in \mathbb{M} capsules may be given with food three times daily. *Cyllin* and *kerol* may be given in the same manner.

A course of *high colonic irrigations*, following the Plombières method, is indicated if mucus persists in the stools despite the above measures. Or it may be given as a preliminary treatment, to be followed by them.

In acute cases, with pyrexia, full doses of *alkalis* (sod. bicarb. and pot. cit.) are very helpful, and should be continued until the urine has been alkaline for 3 or 4 days. The *hexamine group* will then do good in proportion as the infection is focused in the urinary tract, and in proportion as the infection is pelvic rather than vesical. In gall-bladder infection these drugs are also of service, so far as clinical experience goes. To get the greatest service from hexamine in urinary tract infections it is best to keep the urine acid. For this purpose it is considered by many that acid sod. phosph. in grs. xx doses is serviceable. It is well to change the hexamine (grs. v to xv well diluted) for one or other of its derivatives now and again, reverting to the hexamine again later: *cystopurin* = hexamine sod. acetate, grs. xxx; *helmitol* = hexamine with citrate, grs. xv to xxx. *Caprokol* (hexyl-resorcin), grs. ii to x, is also useful.

2. *Local measures*.—Local suppurations will, of course, be dealt with surgically. Reference has already been made to associated disabilities in some cases of urinary infection which also require surgical treatment, as also to the care which must be exercised in dealing on surgical lines with those cases of urinary tract infection which may be regarded as primary. In bowel infections a very useful adjunct in treatment is to endeavour by means of posture, massage and efficient supports to improve matters if enteroptosis be present.

3. *Specific measures*.—There remains to be discussed the use of bacillary vaccines. These should always be regarded as supplemental to, rather than substitutions for, the scheme of therapeutics outlined in (1) and (2). In acute cases vaccines should either be deferred until other measures fail, or very small doses of the vaccine should be given—0.5 to 5.0 million at most, and at intervals decided upon by close observation of the course of the disease. In chronic cases vaccines should always be given a good trial. Sometimes the good effects are very striking, at others little or nothing is achieved as the result of vaccine therapy. In cases which are of long standing, and in which constitutional symptoms are absent, vaccines prove disappointing. But their use certainly seems to assist in rendering patients less toxic, in relieving local symptoms, and in protecting against acute exacerbations. In the case of chronic urinary infections these benefits nearly always stop short of the production of a clear and sterile urine. The graduated method of dosage is the one generally adopted; a series of doses ranging from 5 to 250 million, injected at intervals of 7 to 10 days, is a favourite plan. In very chronic and intractable cases the dosage may well be extended beyond this last-named figure—even to 1000 million. *The vaccine should invariably be autogenous in nature*. If second or any subsequent series of vaccine injections be given, these should be prepared from a fresh culture of the infecting bacillus, and the first doses given should be of smaller size than those which concluded the former series.

THOMAS HORDER.

BACILLARY DYSENTERY

Definition.—An invasion of the large and sometimes the small bowel by dysentery bacilli, often occurring in epidemics.

Ætiology.—No country in the world is free. All ages and both sexes are liable. Natives suffer as well as visitors from the disease. In England the disease is common in asylums. The disease is due to bacilli of the dysentery group. Two well-marked varieties or strains are implicated, namely, Shiga's or Flexner's bacillus. (Further varieties of these are also described, Hiss, Y. Strong's bacillus, etc.) These organisms can be cultivated from the stools in acute cases, but it is a much more difficult matter to obtain them in chronic ones, on some days the organisms being present, on other days absent. Later, they tend to disappear completely, though symptoms may persist.

Pathology.—The lesions are those of a diphtheritic catarrh, the condition attacking the mucous membrane of the large bowel and sometimes spreading into the small (entero-dysentery). The first change is hyperæmia, then œdema, then necrosis, resulting in the formation of a diphtheritic membrane, generally distributed, or in patches, and often of a greenish colour. The dead tissue is then exfoliated, ulcerated areas being left behind. Many of these are superficial, their floor being formed by the submucosa, while others extend deeper, exposing the muscular layers. There is no undermining as in amœbic ulcers.

Symptoms.—Various types of intensity of the disease are met with, acute types, chronic types, the entero-dysenteric type, etc. In the acute form the incubation period varies from 24 to 48 hours or longer; the illness generally comes on suddenly, with pain in the abdomen and an increased desire to go to stool, the motions now changing from a fæculent character to mucus and blood. The temperature rises, and nausea, retching and vomiting are also common. There may be albumin in the urine. The general symptoms are due to the absorption of the toxins of the bacilli. Gangrene of the bowel may develop. In mild cases, fever and serious indisposition may be absent. As the patient recovers, the pain and tenesmus gradually diminish, the temperature falls, the motions become fæculent again, and convalescence is slowly established.

Chronic type.—This appears after an acute attack has passed away. The patient may have been quite well for a time, but then a relapse occurs with a return of the dysenteric symptoms. Further attacks succeed, and the condition passes into a chronic stage, with constant disturbance of the bowels, and the frequent passage of blood and mucus. There may be pyrexia; loss of appetite is common, sweating at nights and emaciation also occur. The stools contain fæculent matter, mixed with blood and slime; there may be as many as 6 or 7 stools a day.

Entero-dysentery.—In this type there is usually no tenesmus, and the stools are not so frequent, the blood and mucus being more intimately mixed with the fæces. It is a very serious type, and toxic symptoms are prominent. The temperature is continuously high, the mouth and tongue are covered with sordes, and the patient passes into the typhoid stage and dies.

Complications and Sequelæ.—Liver abscesses do not occur. Peritonitis may follow an attack with subsequent adhesions. Parotitis and arthritis

occur, and peripheral neuritis has been described. The arthritis is most common in the knee joints, but several joints may be affected at the same time. It is similar in some ways to gonorrhoeal arthritis (see Section on Arthritis). The condition is due to toxic absorption from the bacilli in the intestine.

Diagnosis.—This has to be made from other forms of dysentery. If protozoa be absent at the first stool examinations, then cultivations must be made for the dysentery bacilli. Microscopically, if the exudate be rich in cells, a bacillary case is likely. It is important that the specimen for cultivation should be freshly passed.

Prognosis.—Bacillary dysentery is a serious disease. In some epidemics the mortality is very high. People in poor condition and semi-starved easily succumb.

Treatment.—*Prophylactic.*—A prophylactic vaccine should be adopted for those liable to infection. So far, however, such vaccines have been too toxic for general use. Besredka's vaccine by the mouth was recently used for the troops in Shanghai, and the incidence of the disease was very slight, apparently as a result (Col. MacArthur). As the disease is chiefly spread by water and food, like enteric fever, prophylactic measures similar to those indicated in that disease are indicated.

Curative.—Rest in bed, suitable diet and hot fomentations to the abdomen are indicated. Albumin water, barley water or rice water should be given at first, then later milk. Flexner or Shiga serum, depending upon the organisms present, should be given as soon as possible in all severe cases. Polyvalent sera are also prepared. Doses up to 80 c.c. or more are indicated in severe cases, and may be repeated if required. For mild cases, salines may be given, such as drachm doses of sodium sulphate every 2 hours or so, till the stools become faeculent again, then less frequently. This often suffices. Rogers' hypertonic salines may be tried in fulminating cases.

For chronic bacillary cases, the treatment is very unsatisfactory. Serum and vaccines do not do much good. Diet is all-important, and may keep the disease in abeyance in ordinary cases. Rectal lavage is valuable. It should be controlled by sigmoidoscopy. Where the whole bowel is badly ulcerated, an appendicostomy, or better, a cæcostomy, is justifiable. The latter allows the escape of faeces by the cæcostomy wound, and so gives complete rest to the affected part. The author has had several wonderful cures by this method. Unfortunately even after such operations the disease may continue. If the patient could stand the operation, removal of the whole of the colon (Arbuthnot Lane's operation) might be tried, thus removing the diseased part *in toto*. It is obvious however, to ensure success, that the small bowel and the rectum must be in a healthy condition. The magnitude of such an operation, combined with the poor physical state of the patient, puts it out of court, however.

For AMEBIC DYSENTERY, see p. 237.

CHOLERA

Definition.—A specific disease due to a specific micro-organism, the cholera spirillum, diffused endemically throughout India, and from there, from time to time, becoming diffused to other parts of the world. The disease

is characterised by violent vomiting, purging, cramps and suppression of urine, followed by a febrile reaction.

Ætiology.—The disease exists endemically in parts of India, its principal focus being the delta of the Ganges and the alluvial plain which lies south of its confluence with the Brahmaputra. From here epidemics of the disease have started, and have spread, by the trade routes, even as far as Europe. There was cholera in the Balkans in the war with the Turks preceding the Great War, and cases are met with in Russia from time to time. All races are liable, as also both sexes and any age. The disease is due to Koch's comma bacillus or spirillum, an organism which has its habitat in the intestines. The vibrio measures $1.5\ \mu$ to $2\ \mu$ in length and rather less than $0.5\ \mu$ in breadth; a single terminal flagellum may be demonstrated. It is motile, stains readily with the ordinary aniline dyes, but loses the stain by Gram's method (Gram-negative). A very characteristic growth takes place in stab gelatine cultures, liquefaction commencing at the upper part of the stab and forming a bubble or bell of air. Indol and nitrites are formed (cholera red reaction). Special bacteriological tests must be carried out, however, before distinguishing the true cholera bacillus from other common vibrios.

Pathology.—The germ in the human subject grows principally in the mucosa of the small intestine. The question whether it produces a toxin or not has been much argued. Some authorities suppose it produces an endotoxin, and this causes the gastro-intestinal disturbances which lead to the passage of fluid from the blood to the bowel. Owing to the drain of serum the specific gravity of the blood rises to as high as 1065, or even higher; the alkalinity of the blood is decreased, and its coagulative power altered; there is also a fall in the blood pressure to 80 or lower. As convalescence is established, there is great risk from invasion of the body with secondary contaminating organisms, cocci, bacilli, etc.

A post-mortem rise of temperature is common. Rigor mortis sets in early and may be very pronounced. The blood is thick and tarry, and when the abdomen is palpated a peculiar sticky feeling is noticed; this is said to be diagnostic. The intestines are collapsed and shrunken and the mucosa is swollen and hyperæmic. The liver is congested; the kidneys swollen, ecchymotic and often in a state of acute nephritis; the spleen small and shrunken; the lungs collapsed, dry and anæmic. The general condition of the viscera, apart from the intestines, points to a severe toxæmia or poisoning.

Symptoms.—Castellani and Chalmers describe 5 types of cholera. (1) Ambulatory cases in which, without any signs of disease, the spirillum may be obtained from the fæces; these are genuine carriers of the disease. (2) Choleraic diarrhœa, a variety associated with severe purging, and yellow motions containing the specific germ. Recovery may ensue or the condition may pass into a typical attack of the disease. (3) Cholérine, where the patient is seized suddenly with severe abdominal pains, passes numerous fæculent motions, followed by typical rice-water stools which speedily cease, and recovery takes place without further symptoms. (4) Cholera sicca: the patient becomes rapidly collapsed, and dies before the typical symptoms of diarrhœa and vomiting can appear. The post-mortem and the bacteriological examination of the bowel contents reveal the true nature of the

disease. (5) *Typical cholera, cholera gravis*: the incubation period is from 2 to 5 days.

There are three more or less well-defined stages—(1) The preliminary diarrhœa; (2) the collapse stage; (3) the period of reaction.

1. *The preliminary diarrhœa*.—This stage may set in abruptly, but colic-like pains in the abdomen have usually been present for 1 or 2 days, with some looseness of the bowels. There may be headache, vomiting and depression of spirits.

2. *The collapse stage*.—Once started the diarrhœa increases, profuse liquid evacuations succeeding each other with great rapidity until all faecal and bile-colouring matter disappear, and only a material like rice-water is passed. Cramps of great severity occur in the legs and feet, thirst is excessive and vomiting also results. The patient quickly sinks into a state of collapse, the skin becomes blue, the face pinched and the skin wrinkled like that of a washerwoman's hands. The voice becomes husky, the temperature falls to subnormal and death takes place some 12 to 36 hours after the onset of the attack. The urine is diminished in amount, contains albumin and casts, and uræmia is not uncommon, and is closely associated with acidosis.

3. *The period of reaction*.—If the patient survive the collapse stage and recovery take place, the cyanosis gradually yields, warmth returns to the skin, the heart's action becomes stronger, the stools become less frequent, the urine increases in quantity and the abdominal pains disappear. Even after the appearance of these favourable symptoms, the diarrhœa may return and death take place, or in other cases, a cholera-typhoid stage develops—delirium, rapid feeble pulse, high temperature, oliguria, with subultus tendinum and finally coma.

Complications and Sequelæ.—The most common of these are pneumonia, enteritis and nephritis. Abscesses and suppurative parotitis also occur, while troublesome cramps in the legs may still persist.

Diagnosis.—During an epidemic this is easy, but when there are only a few sporadic cases it is more difficult. A disease that can be confused with cholera is the cholera nostras or choleraic diarrhœa of temperate climes. The choleraic form of malaria also may simulate cholera closely. It is distinguished from it by the presence of malarial parasites in the blood. Certain poisons produce somewhat similar symptoms—arsenic, perchloride of mercury, ptomaine poisoning and certain fungi. To make certain, the stools must be cultivated, and if the case be true cholera, the specific germ will be found.

Prognosis.—This varies in the different epidemics. The disease is a serious one and the prognosis always uncertain. The mortality varies, from 30 to 80 per cent. As a rule it is worse at the beginning of an epidemic than later when the epidemic is waning. Intemperance, debility and old age are specially unfavourable. The more rapidly the collapse sets in the greater the danger. Cases with marked cyanosis and very low temperature, according to Osler, rarely recover.

Treatment.—*Prophylactic*.—The water supply should be pure. Surface wells and surface collections of water are always dangerous, where natives live, because of their habits of defæcating promiscuously upon the soil. Flies must also be destroyed and prevented from entering houses. All persons before going into cholera areas should have a preventive vaccine. Such inocula-

tions undoubtedly reduce the case incidence, though the case mortality does not seem to be influenced.

Contaminated foods must be avoided. The kitchen must be kept clean, flies must be excluded from the larder, and, preferably, the house should be rendered fly-proof. Milk is always dangerous because of the ease with which it becomes contaminated; it is therefore better boiled. Drinking vessels, eating utensils, plates, cups, etc., should be cleaned, after use, in boiling water only, and then dried by heating or with sterilised towels.

Curative.—During epidemics the bowels must receive careful attention. Diarrhoeas and other minor maladies of the stomach and intestines, which often turn out to be cholera, should never be neglected. Salines and strong purgatives should be avoided. Any looseness of the bowels should be treated by astringents, the patient being confined to bed, if necessary. Chlorodyne and other preparations of morphine and opium are invaluable.

The treatment of the attack divides itself into three stages—(1) The invasion; (2) the collapse; (3) the reaction.

1. Antitoxic sera may be tried in this stage. The Japanese believe they have had success by such methods. The patient should be kept strictly in bed, the blinds of the room drawn down, too many bedclothes avoided, and the temperature of the room should be between 70° and 75° F. Macleod recommends for the cramps, moderate and intermittent chloroform inhalations, friction with anodyne liniments, or counter-irritation with turpentine, mustard or camphor liniment. Hypodermic injections of morphine have been tried.

2. During the collapse, failure of the pulse must be energetically met or death quickly takes place. In the early stages alcohol, ammonia or spirit of chloroform may be tried, but preparations should at once be made for intravenous injections of saline. Before this is done an intravenous injection of Rogers' alkaline solution (sodium bicarbonate, 160 grs.; sodium chloride, 90 grs.; water, 1 pint) should be given to prevent the onset of acidosis. Then after this the same authority's hypertonic solution should be employed (sodium chloride, 120 grs.; potassium chloride, 6 grs.; calcium chloride, 4 grs.; water, 1 pint), this being also given intravenously, and the amount required being determined by the specific gravity of the blood—for example, a specific gravity of 1061, 1 pint; 1062, 2 pints; 1063, 3 pints; and so on. These may have to be repeated time after time, until all signs of collapse have disappeared. Glucose or gum acacia injections might also be tried. Potassium and calcium permanganate are recommended by the mouth.

Tomb's mixture of essential oils is alleged to be very efficacious; it may obviate the use of intravenous salines and may relieve suppression of urine.

3. In the reaction stage, any tendency to suppression of urine must be suitably dealt with by poulticing the loins or cupping. For persistent diarrhoea rectal injections of tannic acid may be given. Pneumonia and other complications are to be combated on ordinary principles. The discharges must be disinfected carefully as in typhoid fever and great care must be taken to prevent flies obtaining access to them.

A simple diet should be taken during convalescence, and all over-exertion avoided. A change of air is also indicated with rest from work for a considerable period of time.

G. CARMICHAEL LOW.

DIPHTHERIA

Definition.—A disease caused by the Klebs-Loeffler bacillus (*Corynebacterium diphtheriae*), characterised by a membranous exudate at the site of infection and distinctive sequels of toxæmic origin, the chief being circulatory failure, paralysis and albuminuria.

Ætiology.—Diphtheria is commonest in temperate climes. Human agents are commonly the carriers of the infection and the cause of its endemic prevalence; local conditions, such as dampness, exposed aspects, soil contamination and defective drainage, being merely contributory. In its seasonal prevalence diphtheria closely resembles typhoid and scarlet fever, the maximum incidence falling in the autumn and late winter months. An epidemic tendency is noticeable in years of deficient rainfall, and great epidemics have been preceded as a rule by a series of dry years. Formerly a disease of rural districts, diphtheria is now endemic in most large cities and shows a tendency to local epidemic outbursts. Its heaviest incidence is on children between the ages of 2 and 5 years. New-born infants are rarely attacked. Many cases occur in adults, and rather more females than males are affected.

Catarrhal conditions of the throat predispose to the infection; convalescents from measles and scarlet fever, and in less degree those recovering from whooping-cough and influenza, are liable to contract the disease, which in the case of recent measles or scarlet fever may assume a particularly severe form. A progressive increase in infectivity and severity is often noticed during epidemics. The immunity afforded by diphtheria is short-lived; relapses are not uncommon, and second attacks also occur.

The disease is highly contagious, and infection is by direct or indirect contact. It is seldom air-borne even over a short distance. The organisms reside in the secretions from the nose and throat, in detached shreds of false membrane, and at times in discharges from the ears, the vulva, infected wounds or skin lesions.

Direct infection may result from kissing, or the reception of droplets of fluid ejected by speaking, coughing or sneezing. Indirect infection may be caused by eating or drinking utensils, handkerchiefs, towels, throat spatulas, clinical thermometers, toy trumpets, slate pencils and the like. The diphtheria bacillus readily grows in milk and produces no suspicious changes; milk thus may serve as a vehicle for spread of the disease. There is no evidence that it is conveyed by drinking water. The diphtheria of pigeons, calves, cats and most other animals has not proved communicable to man and is due to a different organism, but virulent diphtheria bacilli have been found in nasal discharges and open sores of horses.

Outside the body, diphtheria bacilli retain their virulence for long periods if protected from sunlight and from currents of air; hence the possibility of transmission by garments, toys and other articles. Sterilisation by boiling water or in the steam chamber is quite effectual.

Carriers.—Convalescents may harbour virulent bacilli in their throats, as also may others who have been in contact with the infection. Most are free from bacilli 4 or 8 weeks after the commencement of the disease, but

in some the carrier state becomes chronic. The presence of bacilli in the throat secretions of carriers is apt to be intermittent. All carriers are not equally effective distributors of the disease; intimate contact and addiction to such habits as kissing, sneezing, spitting and pencil-sucking are important in this respect. The nasal carrier is believed to be an especial source of danger. Among school children 80 per cent. of the carriers are between 5 and 8 years of age, and male carriers are two or three times more common than female. Throat and nose operations on carriers may be followed by clinical diphtheria. In the search for carriers, pallor, unhealthy tonsils, and nasal discharge are important indications, as also a history of recent sore throat. Skin carriers are the subjects of eczematous or impetiginous lesions on various parts of the body. The discovery of bacilli which morphologically resemble diphtheria bacilli does not necessarily prove they are virulent. Bacilli recovered from the throat are rarely harmless, but those recovered from the anterior nares and the skin often prove to be non-virulent when tested on guinea-pigs.

The Klebs-Loeffler bacillus is a non-motile, Gram-positive, non-sporing organism which grows as a diplo-bacillus and shows a great tendency to become segmented or clubbed. The bacilli are slender rods, straight or slightly curved, and of varying length and thickness. In films they often show a characteristic grouping which recalls the letters of the Chinese alphabet. Both long and short forms occur, the length varying from 2 to 6 μ . The long bacilli are the more typical, and are said to be more virulent. The segmented appearance of the protoplasm is relied upon for morphological identification. A rapid diagnosis may be made from smears prepared direct from the throat, but it should be confirmed by examination of a film made from a young (6 to 18 hours) culture on blood serum or Loeffler's medium. Segmentation may be demonstrated by staining with Loeffler's (alkaline) methylene-blue or by Gram's method, but the most characteristic and easily recognised picture is obtained by the use of Neisser's stain (acid methylene-blue), whereby a dark dot is shown at each end of the bacillus and often another at the centre, contrast staining being effected by the use of Bismarck-brown. The following modification of Neisser's method may be relied upon for good and uniform results. Stain in freshly prepared Neisser's stain for 5 minutes; pour off the stain and wash rapidly in distilled water. Immerse in Gram's iodine solution for 2 minutes and again wash rapidly. Stain in Bismarck-brown for 5 minutes. Drain dry and examine with an oil-immersion lens.

Pseudo-diphtheria bacilli, which, although identical in appearance with diphtheria bacilli, are non-virulent, are frequently found in the nose and ear, more rarely in the throat. Another non-virulent organism of the same group is Hofmann's. This appears in smears as a diplo-bacillus, the elements of which are short, squat and wedge-shaped with apposed bases. It stains uniformly throughout, and is shorter than even the shortest varieties of the diphtheria bacillus. These distinctions apply only to young cultures. Hofmann's bacillus does not produce acid in glucose media, and is so further distinguished. The xerosis bacillus, obtained from the conjunctiva, also resembles the true diphtheria bacillus, but it produces acid both in glucose and in sugar media.

The crucial test of the identity of the diphtheria organism is the pre-

vention of the local or general action of an injected broth culture by the previous injection of diphtheria antitoxin into the test animal.

In the throat, diphtheria bacilli are often associated with streptococci, staphylococci, or the fusiform bacilli and spirilla described by Vincent. Of these, streptococci are most important as cases of septicæmia have been found due to them. Diphtheria bacilli themselves rarely become disseminated in the blood stream or internal organs.

Pathology.—The constitutional disturbance caused by diphtheria is toxæmic, toxins but not bacilli being absorbed from the primary lesion, probably by the lymphatics. The extent, thickness, persistence and situation of the membrane determine the degree of toxæmia produced. In the formation of membrane, epithelial necrosis first occurs and is followed by inflammatory effusion from the subjacent tissues. This gives rise to the membrane in which stratified fibrin entangles epithelial cells, blood-cells and leucocytes. Nearly the whole of the process occurs outside the basement membrane. Bacilli are found in the false membrane and necrotic material, but not in the healthy tissues beneath. Recently formed membrane is firm in texture and has a glistening or somewhat gelatinous appearance. The tonsils are the common sites of the first membrane formation, but the faucial pillars, the soft palate, the pharynx, the epiglottis and the larynx may be implicated. Extension from the larynx along the trachea and main bronchi is not uncommon, but coherent membrane is rarely found in the bronchioles. Diphtheritic membrane is much more firmly adherent to the mucous membrane of the fauces than to the epiglottis, the larynx and lower air passages. Its appearance in the cavity of the mouth, on the tongue or lips is rare, and even more rare is its occurrence in the œsophagus, stomach, or small intestine. The conjunctiva and occasionally the vulva, or a cutaneous abrasion or a surgical wound may become infected. In this connection it must be remarked that streptococci and pneumococci can also produce false membrane, but this occurrence is not common.

The secondary broncho-pneumonia of faucial and laryngeal diphtheria is more commonly streptococcal or pneumococcal than diphtheritic in origin.

Apart from the membrane, the morbid appearances in diphtheria are not distinctive. The condition, however, of the heart muscle is of peculiar interest owing to the frequency of severe circulatory failure. Even in cases in which the myocardium appears healthy to the naked eye, special staining will show extensive infiltration of the muscle fibres with minute fatty granules. More gross changes are evident in advanced cases, patches of myocardial degeneration and perivascular aggregations of leucocytes becoming apparent. In severe infections the cavities of the heart may be dilated, the muscle flaccid and friable, and intracardiac thrombi, some obviously ante-mortem, may be found in the recesses of the auricles and ventricles, particularly on the right side.

Fatty granules, similar to those which occur in the myocardium, are found in the adrenals and in the fibres of the diaphragm but not in the skeletal muscles.

The chief lesion in the kidneys is a degeneration of the epithelium of the tubules, but glomerulitis and small blood extravasations may also be present. To the naked eye these changes may not be apparent.

Broncho-pneumonia is not uncommon in extensive faucial and in

laryngeal infections. Emphysema or pulmonary collapse may occur where respiratory obstruction is severe, and massive collapse of the lung may result from paralysis of the respiratory muscles.

In the nervous system, the essential lesion is a parenchymatous degeneration of the peripheral nerves which is curiously patchy in its distribution. Chromatolytic changes are also found in the vagal nuclei and in the anterior cornual cells of the cord. The cerebro-spinal fluid is normal.

The lymphoid tissues of the body often show a reaction, Peyer's patches being swollen and the spleen slightly enlarged. The liver, too, may be swollen from venous stasis and show slight toxic degeneration of its cells.

Petechial hæmorrhages in the skin, serous membranes, heart wall, and diaphragm are characteristic of hæmorrhagic diphtheria. Extensive effusions of blood sometimes occur in the subserous and submucous tissues, in the skin, and in the viscera.

Symptoms.—The incubation period may not exceed 24 hours, more commonly it is 3 or 4 days, but a carrier may harbour virulent bacilli for a considerable time before showing signs of infection. The fauces are most often the site of the disease, next in frequency come the naso-pharynx, the nasal passages, the larynx and trachea. Infection of the genital mucous membrane and of wounds is exceptional and of the skin decidedly rare.

Faucial diphtheria may occur in any degree of severity, from a mild catarrhal inflammation, the identity of which is only established by bacteriological examination, to a widespread infection in which membrane invades not only the whole throat but also the naso-pharynx, nose, larynx, and, rarely, the mouth, either simultaneously or in succession.

Invasion may be characterised by malaise, headache, anorexia and soreness of the throat. Vomiting occurs occasionally and sometimes shivering; rigor is rare. In children, the onset is particularly insidious, discovery of membrane often being the first intimation of the disease. The exudate in mild cases is often limited to a patch on one or both tonsils, sometimes on the uvula or pillar of the fauces, sometimes on the soft palate. More rarely the posterior pharyngeal wall is first attacked. Special characteristics of the membrane are its elevation above the general surface, its well-defined edge, and its glistening or pearl-grey colour. At first it is separable without bleeding, but later free oozing of blood occurs when it is forcibly detached. Multiple patches on the tonsils may, in the early stage, simulate follicular tonsillitis, but the patches tend to spread and fuse; limitation to one tonsil should always arouse suspicion.

Pyrexia is moderate or absent in mild infections, enlargement of the submandibular glands is slight, and the albuminuria so characteristic of grave attacks may be wanting.

When faucial diphtheria is severe it constitutes a very serious form of the disease with a high mortality. The grave form is more common in children than in adults and may develop very rapidly. The membrane is thick, tough, and adherent, sometimes much discoloured. It covers the swollen fauces and may extend widely over both aspects of the soft palate and on the pharyngeal wall. Nasal discharge points to implication of the naso-pharynx and nose. Rarely extension occurs along the hard palate and into the sulci at the sides of the tongue. Secondary invasion of the epiglottis and larynx is not uncommon. The cervical glands become swollen and tender, and

extend and involve the neck in a collar of cellulitis (bull neck). The subcutaneous tissues may undergo widespread necrosis and the skin become thinned and much discoloured. A brownish or bloody nasal discharge excoriates the nostrils and the upper lip. Nasal respiration is obstructed and deglutition difficult. The breath has a sickening odour, and the face is puffy or becomes ashen in colour. The skin is dry and the extremities are cold. A slight general cutaneous oedema may make its appearance. The patient is restless and sleepless but apathetic. Bleeding is easily induced by interference with the edges of the membrane, and epistaxis may occur. Fever is not proportionate to the gravity of the disease; in the worst cases the temperature is subnormal. Albuminuria is usually profuse and the quantity of urine secreted may be very small, but uræmic symptoms are rare. A steady and progressive circulatory failure, characterised by a falling blood pressure and feebleness of the heart's sounds, is an ominous feature. The pulse may become soft, irregular or quite imperceptible. Respiration is rapid and shallow. Vomiting often sets in before the end. Broncho-pneumonia can rarely be recognised by physical signs, but is often present. Death may occur within a week of the onset; sometimes, however, under the influence of antitoxin the membrane clears and the faucial swelling subsides, but acute circulatory failure may still be imminent, death often occurring during the latter half of the second week. In those who escape, widespread paralysis is a common sequel.

Laryngeal diphtheria.—Infection of the larynx may be primary, but is usually a sequel of faucial infection. Essentially occurring in childhood, its frequency increases up to the fourth year of life, after which it progressively declines. The presence of membrane, even in the smallest amount, on the tonsils or fauces will afford a positive indication of the nature of the laryngitis. Failing this a diagnosis is made by swabbing, not the tonsils, but the pharynx or larynx; but treatment must not be delayed pending the result. Hoarseness and croupy cough are early symptoms, soon followed by paroxysms of inspiratory dyspnoea due to laryngeal spasm, with characteristic stridor and recession of the chest wall. During the paroxysms the patient is agitated, sweating and perhaps cyanosed. The cough is loud and croupy. With relaxation of the spasm dyspnoea may cease and the child fall asleep from exhaustion. At first the paroxysms are mainly nocturnal, later they become more frequent and more prolonged, until finally obstruction is continuous and mechanical. Extraordinary recession of the sternum and lower ribs may then accompany the efforts to respire. The body assumes a leaden hue and death occurs from slow asphyxia. In rare instances the paroxysms of dyspnoea and cough culminate in the expulsion of membranous casts of the larynx, trachea or larger bronchi. The absence of toxæmic symptoms when membrane is limited to the larynx and lower air passages is very striking.

Laryngeal diphtheria may run its fatal course in a few days. In infants its duration may be less than 24 hours. In favourable cases the condition subsides under prompt treatment. Should obstruction persist after tracheotomy or intubation, the presence of membrane in the trachea or larger air passages should be suspected; when, however, the bronchioles are blocked, the character of the dyspnoea is quiet rather than violent. Laryngeal diphtheria in a mild chronic form is a rarity, but has been seen. The subjects may probably act as carriers of the disease.

Nasal diphtheria.—Infection of the nose may be naso-pharyngeal or purely nasal. The former is grave, as toxæmic symptoms may be pronounced, whilst localised nasal infection is more often a chronic rhinitis of benign course and low infectivity. In such cases a small patch of membrane may, perhaps, be found on the septum, or a chronic nasal discharge may contain bacilli, although no membrane is visible. Possible implication of the nasal accessory sinuses should be remembered. As already mentioned, bacilli from the nose may prove to be non-virulent. Foreign bodies in the nose have been found associated with persistent nasal diphtheria.

Conjunctival diphtheria is usually the result of direct inoculation, but may extend from the nose. It may simulate a mild, simple conjunctivitis, or membrane may form on the inner aspect of the lids. There is a grave form with extreme inflammatory infiltration of the conjunctiva which may lead to sloughing of the cornea and destruction of the eye.

Vulval, vaginal and preputial diphtheria.—Vulval infection may be secondary to diphtheria of the fauces, infection being conveyed by the fingers, or it may be primary. Sometimes it is seen in puerperal women. It is of insidious onset, and the membrane looks like a slough on the inner surface of one or both labia. The inguinal glands are enlarged, and confusion with erysipelas, chancre, or gonorrhœa is possible. Severe toxæmia may ensue. The vagina may be infected with the vulva. Preputial diphtheria may follow circumcision. Infection of the puerperal uterus and of the male urethra is rare. Infection of the umbilicus may occur in the new-born.

Diphtheritic infection of wounds is not common, and membrane formation on the infected surfaces is not invariable. The wound may merely be dry and grey and the adjacent glands swollen. Bacteriological confirmation is necessary, because streptococci and other organisms may give rise to similar appearances.

Cutaneous diphtheria.—Slight infection of the macerated skin at the margins of the nostrils and mouth is frequent and diphtheritic whitlow is not rare, the finger possibly being infected by sucking it. Sometimes the raw surfaces left by eczema, herpes, or impetigo, become secondarily infected, and membrane may form, but skin diphtheria may occur without this distinctive sign. Extensive gangrene allied to noma has also been attributed to the action of the diphtheria bacillus. Before skin cases are accepted as genuine, rigorous bacteriological proof is essential.

Septic diphtheria.—The ordinary grave case of diphtheria may be looked upon as toxæmic or malignant. The septic type of case is characterised by pulpy discoloured membrane and great inflammatory œdema at the site of infection, accompanied, it may be, by ulceration, cellulitis, or even gangrene. The adjacent lymph glands are much swollen, periaadenitis is marked and suppuration may ensue. Erythematous or measly rashes may appear on the extremities. Constitutional symptoms are severe and the prognosis grave, chiefly, it is alleged, because diphtheria antitoxin has no influence on the septic element.

Hæmorrhagic diphtheria.—Hæmorrhagic symptoms supervening during the acute stage indicate an infection of a severe type. Blood may ooze from the edges of the membrane, and epistaxis occur. This in itself is not necessarily serious, but the tendency to bleed may be more widespread, bruises appearing on the body and bleeding occurring around and along the track of

the antitoxin needle. The conjunctivæ may become suffused with blood, and hæmorrhage may occur from the stomach or bowel. Hæmaturia is rare. Small cutaneous petechiæ are by themselves of most sinister omen. They are insignificant in appearance and easily escape detection on account of their smallness and tendency to occur on the neck and trunk where clothing conceals them.

Blood changes.—A polynuclear leucocytosis is common and reaches its acme at the height of the disease. Sometimes the red cells are in excess of normal and the specific gravity of the blood increased, indicating an oligæmia. Leucocytosis may be absent in very mild and also in very grave infections. The presence of myelocytes is also characteristic, and their appearance in large numbers indicates a severe toxæmia and a bad prognosis.

Complications.—The chief are circulatory failure, paralysis, albuminuria and pulmonary inflammations. Relapse sometimes occurs.

Acute circulatory failure is a justly dreaded occurrence. Apart from asphyxia and from respiratory paralysis it is responsible for all the deaths. In diphtheria, excluding the mildest cases and those in which respiratory obstruction exerts its modifying influence, there is from the first a progressive fall of blood pressure, the systolic readings being affected earlier than the diastolic. Recovery is very rare when the systolic reading falls below 65 mm. The fall in pressure is said to be accompanied by a fall in volume and increased concentration of the blood. Vascular relaxation is believed to account for the early fall in pressure, the effect of myocardial weakness appearing later. The condition culminates in attacks of acute circulatory failure. Where systematic pressure readings have not been taken, minor irregularities and intermissions of the heart's action often afford the first warning. True respiratory or sinus arrhythmia, which is so common in childhood and often is exaggerated in diphtheria, should not be confounded with the condition now under consideration. Tachycardia and bradycardia are both disquieting signs. The heart sounds become modified, the first becoming short and soft and the second somewhat accentuated. Vomiting without obvious cause is always a danger signal. The characteristics of the acute attack are great irregularity and feebleness of the pulse, præcordial or epigastric pain, restlessness, rapid shallow respiration, slight cyanosis and a sub-normal temperature. The mind remains clear. Dilatation of the heart and increase in the size of the liver may be evident. Actual dropsy is rare, but sometimes slight œdema of the face, chest and feet appears. Albuminuria may supervene or, if already present, be much increased; partial suppression of urine occurs. Death often results with great suddenness, and should the first attack be survived, which is unlikely, a second or even a third may prove fatal. Rarely recovery ensues.

Death from circulatory failure is an early sequel of severe faucial infections, occurring at the end of the first or in the course of the second week. Cardiac failure occurring at a later stage of the disease is often associated with severe paralytic phenomena, and in some cases, at all events, is believed to be of nervous rather than myogenic origin. Extra systoles, heart-block and auricular fibrillation have at times been demonstrated.

Diphtheritic paralysis occurs in from 15 to 20 per cent. of cases. It is more often localised than general, and rarely complete in degree. Children suffer more frequently and more severely than adults. As a general rule

the extent and severity of the palsy are proportional to the amount of membrane which was present. Exceptionally, paralysis of diphtheritic type occurs in the absence of recognised infection. The usual time of onset is the end of the third or beginning of the fourth week of the disease, but in grave infections it may even set in before the fauces are clear of membrane. Widespread paralysis rarely declares itself before the end of the fourth week, and paralysis of the ataxic type, which is rare, often does not appear until the second or even third month.

A distinctive feature is implication of the soft palate and the ciliary muscle of the lens. Nasal intonation with regurgitation of fluids through the nose and, a little later, paralysis of accommodation with inability to read small print or to thread a needle are the earliest symptoms. The velum palati is found to be anæsthetic and sluggish or immobile. Its reflex is lost. In the eye, the pupil reactions are generally retained. Ptosis and squint are not uncommon. The knee-jerks, after a period of exaggeration, are lost. The faucial paralysis may in severe cases extend and assume a bulbar distribution, implicating the pharyngeal constrictors and the muscles of the larynx, the patient becoming unable to swallow, phonate or clear the larynx by coughing. Great irregularity of respiration, with paroxysms of dyspnoea, vomiting, and grave circulatory failure may accompany paralysis of this type.

The more widespread form of paralysis commences, like the other, with weakness of the muscles of the throat and eye and often some implication of the larynx. Increasing weakness of the legs and arms becomes evident with numbness and tingling in feet and fingers. Slight cutaneous anæsthesia may be present and sometimes astereognosis. In severe cases the muscles of the face, neck, and spine may be involved and the patient become quite helpless. The onset of paralysis of the diaphragm or of intercostal muscles may be responsible for the occurrence of fatal broncho-pneumonia or pulmonary collapse. Sphincter paralysis is only seen in severe cases.

An ataxic paralysis sometimes occurs. Inco-ordination of the movements of the arms and legs with loss of muscular sense are its chief characteristics. It is often mistaken for cerebellar tumour in children and locomotor ataxy in adults.

The limited form of diphtheritic paralysis is transitory, its duration being measured by days or weeks, but the more widespread paralysis may last for months or the best part of a year before recovery is complete.

Hemiplegia sometimes occurs in diphtheria and is due to occlusion of the middle cerebral artery, usually by an embolus. In most cases the paralysis is more or less permanent. Much more rarely an embolus from the heart lodges in a main artery of a limb, producing gangrene.

Albuminuria is of common occurrence, but in mild or doubtful cases its absence is not sufficient to negative the diagnosis. It is most likely to be found about the tenth day, but appears earlier and in greater quantity in grave cases. In those who recover, its presence is transitory and no grave damage to the kidneys results. At times casts and a little blood may be found in the urine, particularly in toxic or asphyxial cases. Acute circulatory failure greatly increases the albuminuria and may lead to actual suppression of urine. Acetone often appears in the urine during severe attacks.

Pulmonary Complications. — Bronchitis and broncho-pneumonia may

accompany severe faucial diphtheria, but are more common when the larynx is implicated. The cause is more often a secondary infection than the diphtheria bacillus. Febrile disturbance, great dyspnoea, cough, and lividity are the signs which should suggest implication of the lung. Auscultatory signs are often equivocal, owing to laryngeal obstruction or the presence of a tracheotomy tube. Massive collapse of the lungs may occur in paralytic patients and is often mistaken for pneumonic consolidation or pleural effusion. Some degree of acute emphysema is usually present when the larynx is obstructed, and surgical emphysema of the mediastinal and subcutaneous tissues may follow a difficult tracheotomy. As sequels of diphtheria, lobar pneumonia, pleural effusion and empyema are rare.

Otitis media is exceptional and seldom serious. In this respect it stands in sharp contrast to the otitis of scarlet fever. Diphtheritic membrane is sometimes formed in the auditory meatus.

Relapse of diphtheria is rare. It occurs in little over 1 per cent. of the cases and usually is mild, the membrane being limited to the tonsils and rarely spreading to other parts.

Diagnosis.—Every inflamed throat, particularly in a child, should be regarded with suspicion, and clinical diagnosis supplemented by bacteriological examination before antiseptics are applied. Definite membrane on one or both tonsils or adjacent parts of the throat is characteristic of diphtheria. Tonsillar inflammation, if accompanied by hoarseness or rhinorrhœa or albuminuria, is highly suggestive. Although some diphtheritic throats are very œdematous and painful, as a rule pallor of the mucous membrane and absence of pronounced fever are also striking features of the disease.

The differential diagnosis between scarlet fever and diphtheria is discussed on p. 260. Simple tonsillitis is usually bilateral, and the exudate, which is soft and crumbling rather than membranous, is follicular and limited to the surface of the tonsils. Pyrexia and constitutional disturbance are more pronounced than in diphtheria, and the tongue is heavily coated.

Peritonsillar abscess is more characteristic of simple tonsillitis and the secondary tonsillitis of scarlet fever. It seldom occurs in diphtheria.

Vincent's angina may produce a greyish film of exudate on one or both tonsils, and even invade the adjacent parts of the faucial pillars and the soft palate, but the process is rather a shallow necrosis than a true membrane formation. Ulceration may be evident at the centre of the deposit; sometimes it is widespread and destructive. The mucous membrane of the gums and cheeks may also be attacked. The breath has a peculiar and offensive odour, but diagnosis should never be based on this alone. The large fusiform bacilli and spirilla described by Vincent are demonstrated by removing the necrotic film, rubbing a swab on the ulcerated patch, and making a smear which should be stained in Loeffler's methylene-blue for 10 or 15 minutes, i.e. at least three times as long as is necessary for the staining of diphtheria bacilli, or with an aqueous (1 : 200) solution of methyl-violet; or a portion of the exudate may be rubbed up with normal saline and examined by dark ground illumination.

Double infections with diphtheria and Vincent's organisms are not at all rare. Thrush, which produces an exudate like milk curd, is recognised by detection of the characteristic mycelium. It is a disease of infants and greatly enfeebled adults.

Syphilis.—Both in adults with the acquired and children with the inherited disease the inflamed throat of secondary syphilis is a cause of confusion. The throat is painful and full of mucous secretion. Filmly patches appear on the tonsils and pillars of the fauces. The tonsillar glands are swollen and there is little or no fever. The rapidity with which ulceration and perforation of the palate occur in some cases is striking. The diagnosis is made from the history, the presence of other signs of syphilis, failure to find diphtheria bacilli, a positive Wassermann reaction and prompt response to vigorous anti-syphilitic treatment.

Rarer conditions which simulate faucial diphtheria are erysipelatous inflammation of the throat, herpes of the soft palate and lesions due to the action of steam, boiling fluids, caustics and other irritants.

Laryngeal diphtheria.—Croupy cough and stridor in a child will always suggest diphtheritic infection. Examination may show membrane on the fauces. By forcible depression of the base of the tongue with a spatula, the epiglottis may often be seen and membrane possibly recognised on its edge or surface. Rarely fragments of membrane are ejected on coughing, or there may be a history of contact with the disease. All doubtful cases should be treated freely with antitoxin, pending confirmation by examination of a swab taken from the pharynx as near the glottic aperture as possible.

Other forms of laryngitis have to be differentiated. They are (1) the laryngitis of early measles, distinguished by history, catarrhal symptoms, and Koplik's spots. (2) Simple catarrhal laryngitis; in this bacteriological examination is most essential. The voice may be hoarse, and the cough croupy; nocturnal spasms of dyspnoea may occur. Enlarged tonsils and adenoids are often present, and sometimes the history of previous attacks is obtained. (3) The glottic spasm of laryngismus stridulus is also definitely paroxysmal, but although the child crows the voice is not hoarse nor is the stridor persistent. Rickets, tetany and convulsions are the accompaniments in many cases.

Retro-pharyngeal abscess, when low down, produces considerable laryngeal obstruction. Digital examination of the back of the pharynx reveals its presence; sometimes the bulging may be seen on inspecting the fauces.

Rarer causes of laryngeal obstruction are congenital syphilis, œdema of the glottis in renal disease, or resulting from inhalation of steam or other irritants, foreign bodies in the larynx, and papillomatous growths. These forms of obstruction are differentiated from diphtheria by the history, by careful inspection of the fauces, followed by digital examination, by general examination of the patient and by the negative results of bacteriological examination. In adults the laryngoscope will give useful information. Direct laryngoscopy is also available.

Prognosis.—The important indications yielded by determination of the extent and position of the membrane have already been mentioned: the more extensive and more persistent this is, the greater is the risk of severe toxæmia. Cases where the membrane is limited to one, or to parts of both tonsils are likely to be mild; when both tonsils are completely covered the attack is more grave, but recovery is still probable; when the fauces and naso-pharynx are extensively involved, the outlook is very serious. The great mortality of laryngeal diphtheria is due to asphyxia and broncho-pneumonia,

absorption of toxin from this region being small. Diphtheria limited to the nose and not involving the naso-pharynx has a low mortality.

Enlargement of the cervical glands is more or less proportional to the extent of the lesion in the fauces and naso-pharynx, and has the same prognostic importance. The efficiency of antitoxin treatment and the day of its first administration have a most important influence. The mortality is almost negligible when antitoxin is administered on the first day of the disease, but it increases progressively to 18 or 20 per cent. if administration is delayed to the fifth or subsequent days.

Age also has a great effect, the disease being very fatal to children in the first year of life, and much more serious in children under 5 than in those over that age. Septic attacks with much pallor, copious nasal discharge, considerable glandular enlargement and profuse albuminuria have a very bad prognosis.

Hæmorrhagic symptoms, other than slight bleeding from the edge of the membrane and possibly epistaxis, are grave: particularly so, minute cutaneous petechiæ. Cases such as these hardly ever survive. Repeated vomiting after the initial stage, and signs of acute circulatory failure are most ominous. The chief danger of paralysis, when this ensues early, is its association with acute circulatory failure, but paralysis of the bulbar type is in itself very fatal. Failure of the muscles of respiration and liability to broncho-pneumonia and pulmonary collapse constitute the chief dangers of generalised paralysis. If the patient survive, paralysis terminates in complete recovery, but hemiplegia, which is of vascular origin, may be permanent.

Treatment.—*Prophylactic.*—Convalescents should be isolated for not less than 4 weeks from the commencement of the disease, or until three negative bacteriological examinations at intervals of a week have been obtained. The presence of inflammatory conditions or discharges from the throat, nose, eyes or ears is an indication for further detention. Skin eruptions and whitlows should be carefully treated.

The period of quarantine advised is 12 days. This may be supplemented by bacteriological examinations. Children from an infected house should not be allowed to attend school. Contacts in the home or school often become carriers, and should be bacteriologically examined. Clothing and utensils which have been in contact with the sick should, of course, be disinfected.

When diphtheria breaks out in a school or ward, contacts should be examined for unhealthy conditions of throat, nose, ears or skin, and bacteriological examination made in all instances, if possible. Opinion with regard to the desirability of prophylactic injections of antitoxin is not unanimous. The *symptoms* of diphtheria may be prevented in contacts by the injection of 500 units of antitoxin, but this method fails if the subject is already incubating the disease, and only affords protection to others for some 3 or 4 weeks. It should be realised that antitoxin does not prevent *infection*, but only the *toxic* results of infection. It *militates* against active immunisation, and may *produce* a condition of hypersensitiveness to serum, which may have to be used subsequently.

For these reasons, the best authorities are against prophylactic injections of antitoxin in contacts and in favour of repeated examinations for signs of development of the disease, when antitoxin can be administered at once.

In the Schick test we have a means of determining whether an individual is susceptible to diphtheria. If a local inflammatory reaction follows the injection of a minute quantity of diphtheria toxin into the skin, susceptibility to the infection is indicated. One-fiftieth of the minimum lethal dose (M.L.D.) of toxin for a guinea-pig of 250 grammes weight, in 0.2 c.c. of normal saline is the standard dose. At the same time, but at another spot, an intradermic injection of heated, and therefore inactive, toxin is made, to discount a "pseudo" reaction due to the foreign protein in the solution of toxin. The absence of a reaction to the active toxin indicates the presence of more than one-thirtieth of a unit of antitoxin per c.c. in the blood, and is a sign of immunity. The injections are usually made into the skin of the forearms. The reaction takes 24 to 36 hours to develop, and another week to subside. Four types of reaction are possible: (1) Negative, (2) Positive, (3) Negative and Pseudo and (4) Combined Positive and Pseudo. These must be discriminated with care. The best time for reading the test is 96 hours after injection.

Individuals who react positively to the Schick test may be immunised by the injection of 0.5 or 1 c.c. of a toxin-antitoxin mixture, the antitoxin being added to prevent poisonous results from the toxin. By incubating diphtheria toxin with formalin its toxicity is destroyed, although its power of combining with antitoxin is retained. Toxoid-antitoxin prepared in this way is now replacing toxin-antitoxin for immunising purposes. As a rule, three immunising injections are given at intervals of 7 or, better, 14 days. The development of active immunity takes about 6 weeks. This immunity is protracted, but its exact duration cannot yet be specified.

Both for testing and for immunisation it is necessary that carefully standardised solutions should be used. These can now be obtained.

Chronic carriers are a great source of difficulty. The bacilli cannot be eradicated by local application to the throat or by the administration of antitoxin. Vaccines, intramuscular injection of diphtheria endotoxin and spraying the throat with 24-hour broth cultures of Staphylococcus pyogenes, or of lactic acid bacilli, have all been advocated. If the tonsils be unhealthy, they should be enucleated and any adenoids removed; this is often successful. Carriers should spend as much time in the fresh air and sunlight as possible. Before condemning a carrier to prolonged isolation, the virulence of the organisms should always be tested.

General.—The patient should be isolated and strict recumbency enjoined. Diphtheria antitoxin must be injected without delay, the result of bacteriological examination not being awaited in any case in which the diagnosis is reasonably certain. It is very important the patient should receive the first dose of serum not later than the third day of the disease; the earlier it is given the better the result, but at whatever stage the presence of membrane indicates prompt dosage. The amount required depends, not on the age, but on the duration of the disease, the extent of the membrane and the degree of toxæmia. For mild cases, on the first or second day 5000 units is sufficient; in more severe cases, the dose should be repeated in 12 hours or 10,000 units injected at once. In severe faucial and nasopharyngeal diphtheria and in infections of the larynx, 10,000 units should be the initial dose, repeated in 12 hours if the membrane still show a disposition to extend, or the laryngeal symptoms be not relieved. Cases coming under

observation after the third day of illness require larger doses than those seen earlier. In very severe infections and those complicated by pulmonary lesions, enormous doses have been recommended; the advocates of these larger doses claim a diminished mortality, a reduction of paralytic complications and a speedier convalescence.

Antitoxin should never be given by mouth or rectum. Intramuscular injection is more effectual than subcutaneous, and should replace it. In severe, advanced, and hæmorrhagic infections, the antitoxin should be given intravenously, undiluted and at blood heat. Injection should be very slow, through a fine needle. The patient is then wrapped in warm blankets, hot water bottles applied, and the foot of the bed raised, since rigor and collapse may follow. Fifty thousand or more units may be given in this way, supplemented by 20,000 units intramuscularly into the buttock or outer side of the thigh. In cases which do not respond the injection is repeated after 12 hours. Strict aseptic precautions should always be observed.

Antitoxin treatment may be followed by certain sequelæ due to horse serum. These are less frequent when concentrated antitoxin is used. They usually occur a week or more after injection and take the form of erythematous, morbilliform, or urticarial eruptions, appearing first in the vicinity of the puncture. Fever, vomiting, arthritic pains or slight joint effusions may accompany the rash. The tonsils may again become inflamed (angina redux) and albuminuria may occur. The rashes and other symptoms are transient but may recur. Aspirin often affords much relief, and the cutaneous irritation may be allayed by weak carbolie lotions. On rare occasions such grave symptoms as rigor, urgent dyspnœa and collapse follow the injection, and death has been known to occur from syncope. These symptoms are anaphylactic in nature and may occur if the patient has been sensitised by injection of serum a few weeks previously, or quite apart from this. Asthmatics are said to be particularly liable to them. When it is necessary to administer antitoxin in such circumstances, a preliminary injection of 5 minims should be given and the effect watched. If no untoward symptoms occur within an hour or two the full injection may be employed.

Absolute recumbency is essential in the treatment of diphtheria. For the mildest case a fortnight is not too long, in the average case at least a month, and for severe infections longer. When the patient is first allowed to sit up in bed the effect on the pulse should be carefully noted. No patient should be allowed to sit up whose pulse is irregular or who has recently vomited. The detection of paralytic symptoms is also an indication for rest.

Local applications to the fauces and nose are of minor importance. In cases characterised by fœtor the free chlorine lotion is of use. When douching is resisted it is better to omit it altogether.

In laryngeal diphtheria prompt administration of antitoxin and the use of a steam tent will generally obviate the necessity of operative interference; but tracheotomy or intubation should not be postponed, if restlessness, dyspnœa and recession of the chest wall be present, or paroxysmal dyspnœa have supervened.

Intubation is suitable for the milder type of case, but constant skilled supervision is necessary, as the tube may be ejected. As a rule, tracheotomy is preferable, especially if the fauces and naso-pharynx be much involved.

Tracheotomy as a sequel to intubation has a very high mortality on account of the class of case in which it becomes necessary. After tracheotomy or intubation the patient is usually placed in a steam tent and the arms secured by light splints or other means. Cough on swallowing is obviated by using thickened foods or by nasal feeding. A method of feeding with the head lying lower than the body is often successful in intubated patients. If all go well an attempt should be made to dispense with the tracheotomy or intubation tube on the third day, sometimes even sooner. Patients must be constantly watched when the tube is first removed. In cases where the tracheotomy is dry and no secretion occurs, an alkaline spray is useful.

Circulatory failure is treated by removing all pillows, raising the foot of the bed on blocks and applying a binder to the abdomen. The most absolute rest and perfect quietude are essential. A combination of atropine, strychnine and adrenalin has the best reputation as a circulatory stimulant in these cases (atropine sulphate, gr. $\frac{1}{100}$; strychnine sulphate, gr. $\frac{1}{100}$; adrenalin solution, 1 in 1000, M.v). The solution is made up to 10 minims with sterile water and injected every 4 hours or more often if necessary. At the same time, as vomiting often precludes feeding by the mouth, a 5 per cent. solution of glucose in hot normal saline should be given by the bowel. Other circulatory stimulants and brands are also advocated. When marked acetonaemia is present, 10 grains of sodium bicarbonate dissolved in 1 ounce of water should be given by mouth or rectum every 4 hours.

Paralysis calls for careful nursing and feeding, with avoidance of muscular exertion, but patients with palatine paralysis only may be allowed up after 10 days if the condition be stationary. Massage and electricity may be useful during convalescence, but should be avoided in the early stages. Hypodermic injection of strychnine is possibly of some use. The daily administration of antitoxin in doses of 1000 to 2000 units is advocated, but is of very doubtful utility.

During the acute stage of diphtheria and also when albuminuria is present, milk is the best food. Solids may be allowed quite early in convalescence. When swallowing provokes coughing, the milk should be thickened with isinglass or cornflour. When pharyngeal paralysis is present, the patient should be fed by rectum, or better, through a large soft œsophageal tube.

The occurrence of anaphylaxis after injection is best treated by injection of morphine and atropine, or of adrenalin, and by artificial respiration.

CHARLES R. BOX.

TETANUS

Synonym.—Lockjaw.

Definition.—An infectious disease, due to the toxins of the tetanus bacillus, and showing itself by tonic spasm of the masseter and other muscles with paroxysmal exacerbations.

Ætiology.—The bacillus of tetanus is a slender rod 4 to 5 μ in length and from 0.3 to 0.8 μ broad. It is a spore-bearing anaerobe. The vegetative forms are slightly motile, and when stained by special methods show numerous fine flagella arranged all round the bacillus. In material from

infected wounds, and usually in cultures after 24 hours' incubation at 37°·5 C., spores occur. These are terminal, giving rise to the characteristic drum-stick appearance. As cultures grow older the numerical proportion of spore-bearing forms increases, and in very old cultures only spore-bearing forms or spores are found.

Distribution.—In nature the tetanus bacillus is found in the soil of highly manured districts, and in the dejecta of various animals, especially the herbivora, in the intestines of which it exists without causing pathogenic effects. In infected wounds the bacillus occurs with other spore-bearing anaerobes associated with pyogenic cocci, and saprophytic organisms of various kinds. In consequence of its association, in nature and infected wounds, with other organisms, the bacillus is difficult of isolation, as a large proportion of the associated organisms grow with much greater rapidity. Use is made of the fact that the spores will resist a temperature of 80° C. for an hour. Suspected material is inoculated into agar or serum-agar slopes or deep tubes of glucose-agar, and incubated for 48 hours. The culture is then subjected to a temperature of 80° C. for three-quarters of an hour, and subcultures are made on agar plates which are incubated anaerobically. By this means all non-sporing bacteria, and the vegetative forms of the spore-bearers, are killed, and only spore-bearing organisms remain to be dealt with.

The disease follows *injury* to the tissues in most cases, and even when no injury is known to have occurred it is highly probable that some slight abrasion has been present. The term "idiopathic tetanus" has been given to those cases in which no discoverable injury is present. Those wounds, usually of the hands, in which the tissues have been badly damaged rather than cleanly cut, are specially liable to be followed by tetanus infection. Cases have occurred from the use of contaminated gelatin used in subcutaneous injections, and from catgut sutures similarly infected.

Tetanus is more common in tropical than in temperate zones. A special form of the disease, *tetanus neonatorum*, is peculiar to the tropics, and results from sepsis in attending to the child's navel. This variety has occurred in epidemics.

Pathology.—In nature the disease is produced by the introduction of infected material through an abrasion or wound, which may be so minute as to escape detection. Probably there is no such thing as idiopathic tetanus, but infection is possible through the bronchial or even intestinal mucosa.

If the bacilli or spores, free from toxin or from pyogenic cocci, be introduced into an animal, infection may fail to occur, the protection afforded being probably accounted for by phagocytosis, for if spores enclosed in a paper sac be introduced into a susceptible animal infection occurs, as the sac protects the spores from phagocytosis. The presence of pyogenic cocci, other micro-organisms, and the fragments of bone and foreign material incidental to compound fractures and gun-shot wounds, all conduce to the conditions favourable to growth of the tetanus bacillus.

The *period of incubation*, following infection with tetanus bacilli, varies with different animals. In man a period of from 2 to 14 days occurs, but the period may be longer, and as a rule a long incubation period means a more favourable prognosis.

Tetanus toxin.—The tetanus bacillus, like the diphtheria bacillus, produces its pathogenic effects by reason of the soluble toxin it elaborates. Bacterium-free filtrates of cultures, as shown by Kitasato, when injected subcutaneously or intravenously into mice cause tetanic spasms, at first in the neighbouring muscles and later more generally, and death has resulted.

Tetanus toxin is one of the most powerful poisons known, the fatal dose for a mouse of a probably impure toxalbumin being found by Brieger to be 0.0005 mm.

Different degrees of resistance to the toxin are shown by different animals. The horse and man are the most susceptible. On a basis of weight the horse is twelve times and the guinea-pig six times as susceptible as the mouse, while the hen is two hundred thousand times as resistant. The incubation period is shorter when toxin is intravenously injected than when introduced subcutaneously, and is shorter in smaller than in larger animals.

It has been proved that toxin is absorbed by the end plates of motor nerves. This was shown by severing the sciatic nerve of an animal near the spinal cord. The corresponding hind limb was then injected with toxin. A portion of the divided nerve was then placed in another animal and tetanus resulted, while if the nerve were cut distally, and a proximal portion thereof were transplanted, no infection occurred, though in both cases the nerves were equally bathed in lymph containing toxin. And, again, if an excess of toxin be injected into a sound limb only that portion of a nerve distal to a section in another limb shows absorption of toxin. Introduction of a lethal dose of toxin into a nerve such as the infra-orbital, containing no motor filaments, is not followed by characteristic tetanus symptoms.

The toxin passes centripetally up the nerve and affects the motor nerve cells corresponding thereto, thus accounting for the longer incubation period in larger animals. If antitoxin be injected into a mixed nerve, such as the sciatic, toxin is prevented from passing up that nerve; but toxin injected into a similar nerve will act lethally even though a large excess of antitoxin had been previously injected intravenously. In one case, indeed, it was shown that a dose of toxin injected into the sciatic nerve of a highly immunised animal caused tetanus. Possibly these results are accounted for by the now well-known difficulty of bringing antibacterial and antitoxic bodies in the blood to bear on the cells of the central nervous system, a difficulty which has been met, to a certain extent, by the introduction of intrathecal medication.

Immunology.—*Tetanus antitoxin*. Very high degrees of immunity, which persist for a long time, can be achieved, both against large doses of tetanus toxin, and against the living bacilli, by the injection of the toxin into animals. As in the case of diphtheria antitoxin, tetanus antitoxin can protect other individuals against a lethal dose of toxin, and in some cases can prevent a fatal result after symptoms of tetanus have occurred. The action of the serum, as also in diphtheria, is entirely exerted on the toxins, and does not affect the bacilli. The antitoxin is prepared by using the horse, it being the most susceptible animal available, susceptibility to the disease being proportional to the degree of immunity that can be achieved. The antitoxin is standardised by similar methods to those described in the case of diphtheria.

Symptoms.—The incubation period has already been referred to. The earliest symptom is, in the great majority of cases, the so-called *trismus*, or tonic spasm of the masseter muscles. Beginning as a slight stiffness, this increases until the jaws are firmly clenched, the patient being unable to open the teeth. The stiffness may involve the muscles of the neck at the same time as the jaws, or a little later. The facial muscles are affected next, and the facies presents the *risus sardonicus* due to the tension in the frontalis and in the muscles at the angles of the mouth. The muscles of deglutition are another group early affected. There is, from these parts, a steady spread of the spasm to the trunk and then to the limbs. The tonic spasm in the muscles of the trunk may show exacerbation in paroxysms, with resulting postures termed respectively *opisthotonos*, *emprosthotonos* and *pleurothotonos*, according as the muscles of the back, abdomen or one side of the body are in a state of spasm. These paroxysms may be induced by divers irritants, and are agonisingly painful.

The disease is often *apyrexial*, but in some cases the temperature rises with the development of the early symptoms, and not infrequently then shows an *ante-mortem hyperpyrexia* (110° F. has been recorded).

Course.—The course of the disease is variable. Sometimes it is as short as 4 or 5 days, the patient dying of spasm of the glottis, of asphyxiation or of exhaustion. Other cases, less fulminant, last from 7 to 14 days. A few seem to deserve the term "chronic."

Diagnosis.—A relatively trivial disease which may, however, cause some anxiety from its resemblance to the trismus of tetanus, is the fixation of the jaw seen in certain cases of *septic throat* and *septic teeth*, with phlegmonous involvement of the floor of the mouth, periosteum, etc. Careful examination of the mouth nearly always suffices to determine the real nature of these cases, and the presence of enlarged and tender cervical glands assists the diagnosis.

Strychnine poisoning presents features resembling tetanus in that the spasms are very similar in both diseases. But between the spasms in strychnine poisoning the muscles are relaxed, a condition never seen in tetanus. Another point of distinction is the fact that trismus and cervical rigidity never exist alone in strychnine poisoning, whereas they frequently do in tetanus.

In any doubtful case of injury, in which there are damaged tissues, bacteriological investigation of the exudate and of material from the depths of the wound should at once be made.

Prognosis.—This is always grave. The mortality in a large series of cases appears to be nearly 60 per cent. (Hill). Infants and children rarely recover. The absence of fever and a slow development of the symptoms are favourable points. If the patient reaches the tenth day of the disease his chance of recovery is considerably increased.

Treatment.—1. *Prophylactic.*—All wounds of a suspicious character should be well curetted under a general anæsthetic, the raw surface should be thoroughly treated with antiseptic and antitoxin administered.

Antitoxin has for some time been used in connection with wounds infected with road-sweepings, or garden soil, and in America chiefly in cases of wounds connected with Independence Day celebrations, in consequence of which injections a very definite fall in the death-rate resulted.

During the Great War antitoxin has been used on a much more extensive scale. Doses of 500 units were given subcutaneously to every wounded man as soon as possible after the wounds were inflicted, and were repeated at 7 days' intervals until 4 doses had been given. As a result of this systematic use of antitoxin the incidence of tetanus in the wounded, which in the early days of the war had been 16 per 1000, was reduced to 2 per 1000 from the autumn of 1914 onwards.

2. *Curative.*—Keep the patient as quiet as possible, in a dark and noiseless room. Feeding may be impossible by mouth, in which event nasal feeding may be attempted, and if this, too, is impossible because of spasm, recourse must be had to nutrient enemata. The vapour of chloroform is the best remedy by which to control severe spasms, and a mixture of chloral and bromide in full doses should be given between the chloroform administrations. A more or less continuous use of morphine is the alternative measure.

It is profoundly important that no delay whatever should occur in the use of serum. Injections of serum may be made subcutaneously, intramuscularly, intravenously, or intrathecally. The latter method achieves much easier access to the affected nerve cells, and is certainly preferable, though it is usually, and rightly, combined with other methods, the more gradual action of the antitoxin when given by the subcutaneous or intramuscular methods tending to balance the rapid elimination of that given intrathecally. An ordinary lumbar puncture is made and 20 c.c. of cerebro-spinal fluid are replaced by an equal, or even slightly greater quantity, of a high titre antitoxin. In an acute case from 50,000 to 100,000 units may usefully be thus given in the first few days, and subsequently the intramuscular or subcutaneous methods may be resorted to.

Less success has attended the therapeutic use of tetanus antitoxin than is the case with diphtheria antitoxin. This result is largely, if not entirely, accounted for by the relative slowness in the onset of symptoms in tetanus as opposed to diphtheria. The argument for the prophylactic use of antitoxin in every case of a wound contaminated with road material or soil contaminated with animal excreta becomes correspondingly strengthened.

The following scheme of treatment for acute cases is recommended by Bruce :

	Subcutaneous.	Intramuscular.	Intrathecal.
1st day	8000 units.	16,000 units.
2nd „	8000 „	16,000 „
3rd „	4000 „	8,000 „
4th „	4000 „	8,000 „
5th „	2000 units.		
7th „	2000 „		
9th „	2000 „		

ANTHRAX

Synonym.—Wool-sorter's Disease ; Splenic Fever of Animals.

Definition.—An acute infective disease caused by the *Bacillus anthracis*. There are three clinical forms of the disease, according as the lesion is in

the skin (malignant pustule), in the lung (pulmonary anthrax), or in the intestine.

Ætiology.—*B. anthracis* is a large Gram-positive bacillus possessing a capsule. On artificial media it grows in long filaments which, owing to the fact that the filaments do not readily break up into individual bacilli, tend to bend upon themselves and thus cause the outlines of the colony to assume a wheeled appearance that is characteristic.

In the tissues, however, the bacilli occur in straight rods measuring from 5 to 10 μ by 1 to 1.5 μ , the longer forms generally being found in attenuated cultures, and the bacilli found in the gelatinous oedema are usually longer than those found in blood. Flagella have been described arranged regularly round the bacilli, but the organism is usually regarded as non-motile.

In the herbivora, especially sheep and cattle, the disease occurs epidemically and the infection assumes a septicæmic type. The spleen may be two or three times its normal size, and on section may be diffuent. An impression preparation from the cut surface shows enormous numbers of bacilli together with blood cells and mononuclear leucocytes. The liver and kidneys are in similar condition, and the lymphatic system is extensively involved.

The carnivora are relatively immune, especially the dog.

Man occupies an intermediate position, and the disease is always communicated to him directly or indirectly from animals. Two principal forms occur, malignant pustule, a local infection through a cut or abrasion of the skin or a hair follicle, and wool-sorter's disease, an infection starting in the trachea and bronchi from the inhalation of dust containing spores.

Infections of the intestinal tract may occur but are rare. Such infections must originate from spores, as the bacilli do not withstand the action of gastric juice.

Bacteriological Diagnosis.—In a case of suspected malignant pustule direct microscopic examination will usually show the bacilli in the fluid in the surrounding vesicles. Sometimes examination of the sections of the excised malignant pustule is necessary. Cultures on agar will show in 24 hours the characteristic wavy-outlined colonies. Blood cultures in man never show the bacilli until just before death. Putrefaction rapidly destroys anthrax bacilli, hence the recognition of the bacillus in putrefying tissues entails careful bacteriological examination and animal experiments.

A guinea-pig may be inoculated with suspected material and if anthrax be present will usually die within 2 days, and the bacilli may be demonstrated in the spleen.

Ascoli has introduced a thermo-precipitin reaction. The suspected material is boiled with five or ten times its volume of normal saline containing one-tenth of 1 per cent. acetic acid, and filtered, and, when cold, is run on to the top of an immune serum, when, if the serum be properly controlled for specificity, a white ring occurs at the junction of the fluids.

Immunity.—Pasteur, noting that one attack of anthrax immunised an animal, elaborated a method of artificial immunity. He attenuated cultures by growing at 43° C. and inoculated sheep therewith, subsequently injecting virulent living cultures. By carrying out this process of active immunity the mortality among animals was greatly lessened. Marchoux showed that the serum of such animals conferred a certain degree of passive

immunity; and Sclavo, by using a mixture of such immune serum and progressively attenuated cultures and virulent cultures, obtained very high degrees of immunity in the ass. Sclavo's serum is stable, and if given in quantities of 40 c.c. at an early enough stage in the disease is almost always successful.

Formerly the local effects of infection were considered due to the mechanical damage to the tissues by the rapid multiplication of the bacilli. Later it was considered that the tissues were injured by simple deprivation of oxygen. Now the result is considered to be a toxic phenomenon.

I. MALIGNANT PUSTULE.—The site of infection is nearly always upon an exposed part of the body—face or hands or forearms. The incubation period appears to be very short, perhaps not longer than a few hours. A small red papule forms, which rapidly becomes vesicular and then incompletely pustular. By the time vesication occurs there is a surrounding zone of intensely red oedema, becoming a brawny induration by the end of the second day. By this time a ring of secondary vesicles often surrounds the initial lesion, which has now formed a dry and almost black scab, generally raised above the surface of the affected skin. A frequent associated lesion in the case of the arm is lymphangitis, spreading upwards to the lymph glands, which become enlarged and painful. There is rarely much pain at the site of the initial lesion, though there is usually a good deal of itching and tenderness. Fever is almost constant, and in severe cases may be quite high. The patient is then very ill, with intense toxic symptoms. Mild cases occur, however, and in them both the local and the general symptoms are much less marked.

The prognosis turns upon the severity of the symptoms, especially of the toxicæmic state. Death is sometimes very rapid—it may occur within the first week.

In some cases the initial papule and vesicle are ill-marked, but the attendant oedema is excessive (*malignant oedema*). The mortality in this type of the disease is a good deal higher than in the type in which the pustule is well formed.

II. PULMONARY ANTHRAX.—In this variety of the infection the bacilli are inhaled with dust from infected hair or wool. The result is the rapid development of fever, generally ushered in by a rigor, with very intense toxic symptoms and the signs of bronchitis. Cerebral symptoms develop with great weakness. The whole course of the disease may be very short, even as brief as 24 hours. Recovery probably never takes place, even if the diagnosis has been made at an early stage.

III. INTESTINAL ANTHRAX.—This is probably the least common form of the disease. The infection is due to eating meat or drinking milk from animals suffering from splenic fever. The symptoms are those of a severe gastro-enteritis—fever, vomiting, diarrhoea and intense weakness. The spleen is enlarged. This form of the disease has been found to occur in small epidemics. The mortality is high, though not so high as in II.

Treatment.—(i.) *Prophylaxis* consists in the specific immunisation of animals subject to the disease, and in the careful disinfection of all skins, hair and wool, before these are handled in any industrial occupation.

(ii.) *Curative*.—The anthrax pustule should be excised immediately it is discovered and recognised, pure carbolic acid being then applied to the

raw surface, which is now fomented continuously. A full diet is given with stimulants, and the patient is kept in bed with complete rest. The use of anthrax serum should be as prompt as possible, in the manner already referred to. (See also p. 36).

THOMAS HORDER.
JOHN MATTHEWS.

TUBERCULOSIS

Definition.—Infection of the body by *Bacillus tuberculosis*, leading to lesions which are characterised by tubercles, microscopic or macroscopic, themselves undergoing changes leading to caseation, necrosis, ulceration and calcification, and having in close association with them varying degrees of fibrosis. The lesions of tuberculosis form the histological and anatomical basis of a large number of diseases which differ according to the organs affected, the extent of the lesions and the degree of resistance to infection shown by the tissues.

Ætiology.—THE *BACILLUS TUBERCULOSIS* (Koch, 1882).—This is regarded by most bacteriologists as a member of the *Streptothrix* group of micro-organisms; that is to say, the bacillus found in tubercular lesions is considered to be the bacillary form of an organism allied to the *Streptothrix*. The other phases in the life-history of the micro-organism are not met with in the actual disease-process, but may be demonstrated in old cultures and in certain experimental lesions. This view of the essential nature of the tubercle bacillus harmonises with our knowledge of its great power of resistance to various destructive agents; it also explains many of the tissue changes occurring in the disease, the latency seen in many cases of infection and the chronicity of many others. The bacillus measures 3 to 4 μ in length as an average, is slender, and when isolated from secretions or tissues is usually bent or curved, and tends to lie in small groups. It is "acid fast" in its staining reactions, allowing of easy recognition; but it grows very slowly outside the body, requiring special media for the purpose of culture. The bacillus is capable of living for several months in dried sputum, and may be cultivated, or may be made to cause disease in susceptible animals, when obtained from the dust of ordinary living-rooms. The gastric juice does not destroy the bacilli, nor does the process of decomposition going on in dead tissues over a period of many weeks. The clinical importance of these facts is obvious. In contrast with these examples of resistance may be mentioned the fact that direct sunlight has a rapid lethal effect upon the micro-organism; so also has a solution of carbolic acid, of strength 1 : 20.

Known differences exist between the bacillus causing tuberculosis in man, in cattle, and in birds respectively. The *avian* form appears to be of little importance. The *bovine* type would appear to cause about 10 per cent. of all cases of tuberculosis in man. In children, the bovine type is found relatively more often. The *human* type of bacillus is less virulent to cattle than is the bovine type, but—though this cannot be made the subject of experiment—the bovine type is probably as virulent to man as is the human type. Of young children dying with primary abdominal tuberculosis, the

fatal lesions, in nearly half of all cases, have been referred to the bovine bacillus. Again, in both children and adolescents suffering from tuberculous adenitis, a large proportion of the cases examined could be referred to the bovine bacillus. Lastly, in lupus, about half of all cases appear to be referable to the bovine type of *B. tuberculosis* (Royal Commission on Tuberculosis).

SOURCES OF INFECTION.—There are two great sources of infection of tuberculosis—phthisical sputa and tuberculous milk. Sources of minor importance are urine and feces containing the bacilli as the result of active lesions in the urinary and intestinal tracts, and the flesh of tuberculous cattle eaten as meat. But the main source of the infecting bacilli of the human type is undoubtedly dried human sputa. Nuttall found that from 2 to 4 billion bacilli were expectorated in 24 hours by a patient whose phthisis was only moderately advanced. These bacilli are scattered freely in dust when the sputa become dried, and they lie about the surface of the patient's body, or they are projected directly into the air along with particles of moisture when patients cough or sneeze or even speak loudly.

Of the bovine type of bacillus it is probably not an exaggerated estimate to say that some 25 per cent. of all dairy cows in this country are tuberculous. In New York, Hess found tubercle bacilli in 16 per cent. of the 107 specimens which he examined.

Modes of Entrance of the Bacillus into the Body.—Although there are some other channels and modes of entry that have theoretical interest, the two chief ways by which the body is infected are undoubtedly ingestion of the bacilli by the alimentary canal and inhalation of them by the respiratory organs. Compared with these two, all other avenues of infection are trivial.

1. Ingestion.—Infection through the intestinal mucosa is considered to be the most common mode of production of tuberculosis in children, the main source of the bacilli being contaminated milk. This conclusion has the confirmation of clinical and post-mortem observations, as well as the support of experimental work by Behring, Calmette and others. Of late years, however, Ghon has adduced facts which suggest that, even in little children, infection may be much more often brought about by inhalation than was formerly thought. Ghon's observations have been confirmed by Eastwood and Griffith, and by Canti.

Another channel of entry by ingestion is the tonsils; tubercle bacilli have been demonstrated by Hugh Washam and others to pass through the tonsillar tissue to the cervical lymph glands. The tonsils are themselves rarely affected.

2. Inhalation.—Primary infection by the route of the air passages is difficult of proof, and, indeed, some authorities regard it as negligible compared with (1). The great frequency of respiratory tuberculous lesions, however, and the incidence and mortality-ratio of pulmonary tuberculosis in ill-ventilated districts and buildings, are points difficult to explain satisfactorily without the assumption that in the majority of these cases infection takes place by inhalation. The statistics relative to contagiousness in tuberculosis institutions are conflicting.

3. Inheritance.—Inheritance of tissue-susceptibility to infection by tuberculosis is a definite fact. But inheritance of tuberculosis is problematical, if by this is meant the transmission of tubercle bacilli in the spermatozoon.

or in the ovum. In the few cases of "congenital tuberculosis" that have been authentically described, the transmission has generally been from a diseased placenta to the blood of the fœtus.

4. *Skin inoculation*.—This is of little more than theoretical interest. Post-mortem warts (*Verruca necrogenica*) are occasionally of tuberculous origin. Czerny, the surgeon, reported a couple of cases of inoculation during skin transplantation.

Among other *etiological factors* the chief is undoubtedly the *inherited tissue-susceptibility* to infection already referred to. The exact nature of this susceptibility is not known, but its existence is one of the cardinal facts of clinical medicine. *Sex* seems not to be a factor. *Racial differences* in susceptibility are noticeable, though the distinction between morbidity-incidence and mortality-incidence must be made here—the former is high in the Irish, the latter in negroes. In the Jews, though the disease is common, the mortality-incidence is low. *Trauma* is definitely known to induce pulmonary infection, or, perhaps it should be said, pulmonary spread of the disease. All *occupations* tending to inhalation of dusty particles, and those which keep the *workers* in ill-ventilated and badly-lighted rooms and places, increase the liability to tuberculosis, especially of the pulmonary kind. If *bad economic conditions* concur with either of these the liability is increased. *Debility*, whether the result of acute illnesses, or caused by pregnancy, parturition, prolonged lactation, or exhausting modes of life generally, increases a natural susceptibility, and gives an acquired susceptibility when no hereditary weakness is present. Tuberculosis is not infrequently a *terminal infection* in such diseases as diabetes, cirrhosis of the liver, leukemia and chronic nerve affections such as tabes dorsalis, etc. *Recurring and chronic respiratory catarrhs* seem at times to lower the local resistance to tuberculosis, though it is often matter for comment that so many patients with emphysema, asthma and chronic bronchial catarrh live for many years without developing pulmonary tuberculosis, provided they inherit no special tissue tendency to infection by the bacillus.

INCIDENCE AND MORTALITY.—The healthy human body is considered to be relatively immune to infection by the bacillus of tuberculosis. Against this statement, however, it must be said that, whether from the ubiquity of the causative germ, or from one or more of several factors enumerated in the preceding paragraph, some 70 to 80 per cent. of all adult cadavers carefully examined in Western countries show lesions due to the bacillus. It is said, too, that one-seventh of the whole race dies as the direct result of tuberculosis. The disease is one of "low resistance," this being the result either of inherited predisposition or of acquired loss of resistance, or of both of these.

The results of infection are of great variety and of all grades of intensity. The variety depends upon the tissues affected, and the route of spread of the infection. The intensity depends upon the degree of relative virulence shown by the bacillus, and the amount of resistance shown by the patient. Tuberculosis may exist without appreciable disturbance to health, and the lesions produced may be commensurate almost with the whole length of a patient's life. On the other hand, the infection may cause an illness of the most severe character, killing the patient in a few weeks. The results of infection are described elsewhere in this book under appro-

priate headings, but general infection leading to the condition termed general tuberculosis is included in this article.

Diagnosis. THE ISOLATION AND RECOGNITION OF THE BACILLUS.—In all doubtful cases of tuberculosis this is a point of vital importance. Clinical evidence of the existence of the disease, however complete it may seem to be, must never lack the confirmation of bacteriological proof, whenever this is possible. ("Physical signs are the signs of conditions, not of diseases.") Seeing that the only radical proof of the existence of the disease is the demonstration of the bacillus in material derived from the patient, attention must first of all be directed to this investigation. By comparison with this demonstration, even the most definite "reaction" to one or other of the tuberculin tests, or the most strikingly positive result with the complement-fixation method, or an abnormally low opsonic index, is untrustworthy. It behoves the practitioner, therefore, to watch jealously for any material that may be available for bacteriological use, and to be quite certain that such material is not obtainable before falling back upon indirect clinico-pathological evidence (see below) to support the diagnosis.

In cases of suspected phthisis, every effort must be made to secure sputa, and it may be necessary to check a habit of swallowing expectorated material. The single, isolated plug of mucus, which is often expectorated in the early morning, should not escape attention. In little children sputa, as such, are usually absent, but if vomiting occurs in association with lung disease the vomit should be searched for fragments of sputa. In suspected disease of the kidney or urinary tract, the urine must be collected carefully and submitted to examination. Cases of albuminuria or of hematuria, in which there is not clear evidence of diffuse nephritis, should raise the question of tuberculous disease of the kidney. The fæces should be scrutinised in doubtful tuberculosis of the peritoneum or bowel. If any puncture-fluid is obtainable—as from the pleura, the spinal theca, or a joint—this is valuable for investigation in any patient suspected of tuberculosis.

The methods of dealing with these materials are not difficult, though they require thoroughness and patience when the bacilli are present in scanty numbers. The very different significance to be attached to a positive as against a negative result must never be lost sight of; the former affords proof of the existence of a tuberculous lesion, the latter gives at most a presumptive evidence against it.

In dealing with sputa, the original carbol-fuchsin method of Ziehl-Neelsen should first be tried. If the results, after carefully searching 3 or 4 films for half an hour, are negative, the sputa should be shaken up thoroughly with ten times its bulk of carbolic acid, of strength 1 : 20, allowed to sediment, the supernatant fluid run off, and films made of the residue. If the sputa are seen to be thin and watery, this method is likely to give a negative result. If so, one of the recently introduced digestion methods may be used—either pepsin and hydrochloric acid, or "anti-formin." The use of the last-named substance, consisting of a mixture of equal parts of bleaching powder solution and a 15 per cent. solution of caustic soda, is found by some workers to give excellent results. An amount of this fluid, equivalent to about one-fifth of the bulk of the sputum, is mixed with it, allowed to act for 3 to 4 hours, the mixture centrifugised, and the deposit dealt with by one of the staining

methods in ordinary use. The bacilli are, by the disintegrating action of the "anti-formin," isolated from the albuminous vehicle and concentrated in the deposit.

Urine is best dealt with by the carbolic acid method (*v.s.*), subsequent centrifugalisation, and staining of the deposit. The smegma bacillus (also acid-fast), which may be present if the specimen has not been obtained by catheter, is differentiated by allowing the stained films to remain in alcohol for ten minutes; the tubercle bacillus is not decolorised. In *pus*, the search is much facilitated by the use of "anti-formin," and this is a useful adjunct in the examination of *fæces* also. A patient suspected of tuberculosis of the bowel often suffers from diarrhoea; when this is the case, Emery's suggestion of giving sufficient opium to cause a solid stool is useful. The superficial parts of the motion are most likely to yield the bacillus, and are dealt with accordingly.

Puncture-fluids very frequently give negative results to ordinary microscopic examination, on account of the scantiness of the bacilli in them. However, the clot (if such occur), or the centrifuged deposit, should always be searched thoroughly, as the demonstration of even a few bacilli of undoubted morphological characters is decisive. Failing this demonstration, the fluid must be used for inoculation purposes, a guinea-pig receiving a liberal amount (not less than 10 c.c. if possible). The inoculation method of diagnosis is, of course, available for the above materials also, as a final test.

The demonstration of tubercle bacilli in *the blood* has received attention of late years, but with widely different results in different hands. Reputable authorities state that bacilli can be seen in stained films in a very high percentage of all cases of tuberculosis, wherever the lesion may be. Others fail to confirm these results. There is nothing *a priori* against the possibility of such findings, seeing that we know tuberculous patients excrete bacilli in their urine even when the kidney is not itself involved, showing that the bacilli pass through the circulating blood. But it may be that the number of positive results on blood examination is directly dependent upon the time employed in searching the slides, in which case the search and its results may have a scientific interest only. Unless some simple method can be devised, which will obviate the needle-in-a-haystack conditions imposed by the examination, it is not likely to prove of practical value. It must be remembered that the medium is a difficult one to work with, and that the sight of a single bacillus never carries utter conviction to the critical eye. Unfortunately, in general tuberculosis, in which form of the disease an examination of 5 c.c. of blood from a vein often yields several bacilli of unquestionable character, we are dealing with (at present) an incurable condition.

Indirect Methods of Diagnosis.—These depend upon the presence in the tissues of certain sensitising and immunising substances. They are indicated in doubtful cases of tuberculosis in which no material is available for investigation by direct methods (see above). The relative values of these methods are still under assessment; at present their values are probably in the order of their description here.

1. THE TUBERCULIN TEST.—The test depends upon the fact that infection by the tubercle bacillus renders the tissues supersensitive to the

toxins of the bacillus, if these be introduced into it artificially. This supersensitiveness is shown by the production of certain "reactions" which are recognisable and are regarded as more or less "specific" in their nature. The test is performed in three ways.

(a) *The subcutaneous test* (Koch's test).—A series of three doses of "old tuberculin" is prepared, 0·0025, 0·005 and 0·01 c.c. (0·25, 0·5 and 1·0 mgrm.), respectively. These are injected at successive intervals of 48 hours, the patient being kept in bed and with 4-hourly temperature records. If any reaction follows the initial dose, the second dose is halved; so also for the second and third doses. The most certain positive result consists in obtaining an increased reaction to a second dose of the same size as the preceding one. A "focal" reaction, *i.e.* some exacerbation at the site of the suspected lesion, is of greater diagnostic value than a mere "general" reaction, *i.e.* pyrexia and malaise.

(b) *The skin test* (Pirquet's test).—This is best employed quantitatively. Three or more strengths (*e.g.* 25, 50 and 100 per cent.) of a solution of old tuberculin are rubbed lightly into the skin of the arm, which has been previously scarified. The appearance of papules and erythema at the site of vaccination constitutes a positive reaction.

(c) *The eye test* (Calmette's test).—A drop of a 1 per cent. solution of old tuberculin is introduced into the conjunctival sac. A positive reaction consists of congestion and more or less exudate, the caruncle being specially affected.

Of these tests there is little doubt that the subcutaneous is the least equivocal in its results. Its great disadvantage is that it cannot well be undertaken in febrile patients. But it is more likely than either of the two other tests to indicate an active as against a "quiescent" or "arrested" focus. It must be confessed that in actual practice none of these tests is very helpful. In some cases of undoubted tuberculosis, especially of the acute and generalised kind, all three tests may be negative. But the chief fallacy appears to be concerned with the fact that the supersensitiveness upon which the tests depend may exist in patients who have had tuberculous disease many years previously (*e.g.* adenitis in childhood), but in whom the disease now under diagnosis is not tuberculous.

2. THE COMPLEMENT-FIXATION TEST.—This test is analogous to the Wassermann test for syphilis. It is claimed by some workers that it is positive in over 90 per cent. of cases of tuberculosis. The difficulty seems to be that it cannot be relied upon to distinguish an active lesion from one that is not active. Seeing that old and caseous tuberculous lesions exist in such a large proportion of all persons likely to be tested, and that these old lesions still suffice to give the complement-fixation test, its value is quite doubtful unless undertaken in a quantitative manner.

3. THE TUBERCULO-OPSONIC INDEX.—An abnormally low, or an abnormally high, opsonic index to the tubercle bacillus is considered by many authorities to be strong presumptive evidence that the person tested is tuberculous. The limits outside which this probability exists are 0·8 and 1·2. Daily variations in the index, and changes in it as the result of exercise, increase the probability that active tuberculosis is present.

4. CYTOLOGICAL EVIDENCE OF TUBERCULOSIS.—Another and very useful evidence of tuberculous infection is to be obtained in cases of pleural,

and perhaps of meningeal exudates, by estimating the relative numbers of polymorphonuclear cells and of lymphocytes. It is found that, in pure tuberculous infections, the cell exudate is largely, and often almost entirely, lymphocytic in character. In pyogenic infections it is very largely polymorphonuclear; in mixed infections (tubercle with pyogenic infection) the cell-exudate is also of a mixed character.

Treatment.—This is prophylactic and curative.

1. **PROPHYLACTIC.**—The widest possible view should be taken of the preventive measures which are necessary in order to stamp out the disease. If, as seems certain, the three dominant factors in the persistence of the disease are—(i.) the inherited tissue-susceptibility; (ii.) the bacillus; and (iii.) bad hygienic and economic conditions of life, it is clear that the problem is not a simple one.

(i.) Families having an inherited tendency to tuberculosis should recognise the fact earlier and more thoroughly than is usually the case. The upbringing of the children needs special care, and occupations should be chosen for them when they reach puberty which keep them in the open air. Climatic considerations are also of importance in the case of these families.

(ii.) As already stated, the two great sources of the tubercle bacillus are the dried sputa from infected pulmonary cases and tuberculous milk. The former of these is both a public and a private concern—the latter is almost entirely public. Between the position of almost entire neglect on the part of health boards with regard to the purity of the milk supply, and the elaborate precautions of faddists which, if put into operation, would kill the milk industry altogether, there lies a middle course of ordinary cleanliness and reasonable care, the following of which would probably reduce the danger of milk infection by 60 or 70 per cent.

(iii.) This resolves itself into a series of sociological questions.

2. **CURATIVE.**—*Non-specific measures.*—These consist in efforts at improving the patient's nutrition so as to increase the tissue-resistance to the infection—ample fresh air, plenty of good food, bodily and mental rest and exercise undertaken in graduated fashion under expert supervision. Details of all these measures are given in the article dealing with pulmonary tuberculosis (p. 1089).

Specific measures.—The use of tuberculin is considered in the article upon Immune Therapy (p. 47).

GENERAL TUBERCULOSIS

Synonym.—Acute Miliary Tuberculosis.

Definition. A disseminate form of tuberculosis, giving rise to a very severe and fatal disease analogous to the septicæmias in pyogenic infection.

There are three clinical forms of the disease, according as the symptoms are chiefly referable to the lungs (the *pulmonary form*), or to the brain (the *meningitic form*), or are those of a general infection without focal signs. This latter form is often termed the *typhoid form*. The pulmonary form is described in the section dealing with pulmonary tuberculosis. The meningitic form is described in the section on meningitis.

Symptoms.—The *general* or *typhoid form* resembles typhoid fever very

closely. There is usually a period of vague ill-health—as there is in typhoid fever—preceding the more severe illness. When the latter develops there is headache, insomnia, a soft but frequent pulse, rapid respirations, a dry tongue, slight cyanotic flush and pyrexia, which is usually less continued in character than in typhoid fever. Not infrequently the temperature curve is that of a quotidian intermittent fever. In a few cases the rise of temperature takes place in the morning instead of in the evening, a feature not infrequently seen in other pyrexias of tuberculous origin, though not confined to these. Progressive loss of flesh takes place, and also anæmia, but this latter condition may only be found by blood examination, the dusky flush of the face often making the blood state on mere clinical examination. Towards the end of the illness suspicious signs of one or other of the more focal manifestations of the infection often arise: copious fine râles over the lungs, tumidity of the abdomen with palpable enlargement of the spleen and liver, or cerebral symptoms suggestive of meningitic involvement.

Diagnosis.—As the term “typhoid form” suggests, the disease resembling general tuberculosis most closely is typhoid fever. During the first week or even during the first two weeks diagnosis may be very difficult. In favour of typhoid fever are the persistence of headache, the presence of epistaxis, relative infrequency of the pulse-rate, diarrhoea and early tumidity of the abdomen. In favour of tuberculosis are a frequent pulse-rate, early cyanosis and intermission in the temperature curve. There is leucopenia in both diseases. A positive blood culture occurs during the first week in most severe typhoid cases, and agglutination with the patient's serum may reasonably be expected after the end of the first week.

Course and Prognosis.—The disease is invariably fatal, and usually within a period of 6 weeks from the onset of fever and symptoms directly referable to the disseminated infection. A few cases last as long as the eighth week, and the writer has seen a well-authenticated case in which the patient lived until the middle of the tenth week.

Treatment.—This is entirely palliative, there being no specific measures at present known to check the progressive nature of the infection, or its lethal issue.

THOMAS HORDER.

LEPROSY

Definition.—Leprosy (*Λεπρός*, scaly) is a bacillary disease, peculiar to man, associated with characteristic lesions which attack either the skin and mucous membranes (nodular type) or the nerves (anæsthetic type).

Ætiology.—The disease is a widespread one, occurring in many parts of the world, Europe, Asia, Africa, West Indies, Pacific Islands, etc. All races are liable. The disease is not hereditary; it may attack any age or sex. It is now admitted that the causative agent of leprosy is the *Bacillus lepræ*, discovered by Hansen in 1874. The bacillus is non-motile, and is acid-fast, staining like tubercle by Ziehl-Neelsen's method. There have been numerous claims of success in cultivating the organism, Rost, Clegg, Williams, Bayon, etc., all having reported successes; Fraser, on the other hand, has failed, and as the successful investigators are not agreed

as to whether the bacilli cultivated by each of themselves are similar, doubt must be expressed as to all the results. It is not known how the disease is spread. Some suppose sexual connection plays a considerable part, and this is very probable. An intimate contact is at any rate necessary.

Pathology.—The lepra bacillus may be found in any of the tissues of the body, but has a marked preference for the skin, the nasal mucosa and the nerves. The type of lesion produced in the different viscera is that of an infective granuloma-like tubercle.

Symptoms.—There are three main types of the disease—(1) Nodular leprosy; (2) anæsthetic, neural or nerve leprosy; (3) mixed leprosy.

1. *Nodular leprosy.*—The incubation period is uncertain; in many instances the virus may remain latent in the body for years without giving rise to any of the symptoms of the disease. There are recorded instances, on the other hand however, of persons developing the disease a few weeks or months after coming into an infected area.

Prodromata are usually marked—irregular rises of temperature, rigors, lassitude, drowsiness, diarrhoea and profuse sweating. These may be slight, and are not absolutely pathognomonic of the disease. The first positive evidence is the primary exanthem or macular stage, which shows itself as a slightly raised, shiny, erythematous eruption. This may then disappear, leaving only a slight brownish discoloration. Fever, however, recurs with a fresh eruption, and after one or two recurrences the characteristic nodules or tubercles appear, often on the site of the old macular rash. They increase in number until the patient may be nearly covered with them. The hair is often lost from the eyebrows, the mucous membrane of the nose becomes thickened, and the larynx and the eyes may also be attacked. The face acquires what has been described as the leonine aspect—pendulous cheeks, lobes of ears enlarged, etc.

The further history of the nodules varies; they may remain almost stationary, or increase very slowly, or disappear, or more commonly break down, suppurate and form ulcers. When this occurs the destructive process may spread, large areas being affected; ulcers may form on the eyes, causing blindness, or the larynx or pharynx may be destroyed.

2. *Anæsthetic leprosy.*—Prodromata are less marked; feelings of depression, chilliness and malaise, with shooting pains in the ulnar and peroneal nerves may be encountered. In other instances, numbness of the hands and feet is the first sign. Maculae, either beginning with erythema, or with pigmentation, or with a diminution of pigment, not raised above the surface, with loss of feeling, and hair, and sweating, giving rise to anæsthetic patches, are another method of commencement.

A quiescent stage may now set in with no further signs, but finally definite nerve lesions appear—paralysis of the muscles of the hypotenar eminence, contractions of the fingers, wasting of the interosseal muscles, etc. Bullæ may arise, burst and form ulcers; the bones become necrosed, and are cast off whole or in pieces, or in other cases interstitial absorption leads to shortening of the fingers or toes, a portion of the nail being left as a horny peg at the end of the stump. In this way all the fingers and toes may disappear. The fifth and seventh cranial nerves are sometimes attacked.

3. *Mixed leprosy.*—This may start as a nodular case, and then extend to the nerve trunks, or the nervous symptoms may appear first and be

followed by the nodules, or both sets of symptoms may develop together.

Diagnosis.—The lepra bacilli can easily be demonstrated in the nodular cases, either in the nasal secretion or from the juice squeezed out from one of the tubercles; in the nerve cases they can seldom be found. *Lupus vulgaris*, tuberculosis of the skin, syphilis and yaws have all been mistaken for nodular leprosy, while syringomyelia, Morvan's disease (analgesic whitlow), progressive muscular atrophy, peripheral neuritis, ainhum and Raynaud's diseases have similarly been confused with the anæsthetic type.

The bacilli of leprosy occur principally in the lymph spaces, and the characteristic feature is the enormous masses in which they occur; giant cells are generally absent. These points help to differentiate it from tubercle.

Prognosis.—This is by no means good. As a rule the dictum "once a leper always a leper" holds good, the malady gradually going from bad to worse even in spite of treatment. Trinidad observations give an average duration of life of 6½ years for the nodular, 10 years for the nervous, and 9½ years for the mixed form. Periods up to 20 years have even been given for nerve cases. If the larynx be attacked early, or if there be visceral involvement, the prognosis is very bad.

Treatment.—Although it is not known how the disease is spread, manifestly intimate contact with lepers must be dangerous. Lepers must be excluded from acting as cooks, waiters, and in similar employments. Segregation properly and humanely carried out is the best thing, both for those who are affected and for those who are not. The disease may be greatly diminished by such measures. As regards medicinal treatment, general hygienic measures are to be adopted first, then chaulmoogra oil (oleum chaulmoogræ, synonym oleum gynocardia), an oil expressed from the seeds of the *Taraktogenos Kurzii*, King (N.O. *Bizineæ*), or some of its derivatives should be tried. Recently the oils expressed from *Hydnocarpus Wightianus* and *H. anthelmintica* have been found to be as good, if not better than the former, and are being extensively used now. They seem to be of a similar composition. The crude oil can be given by the mouth, in 10-minim doses, t.i.d., and then gradually increased to 1 or 2 drms. in the 24 hours. It has also been given intramuscularly; care must, however, be taken that the needle does not penetrate a vein, as otherwise fatal fat embolism may occur. Antileprol, a purified chaulmoogra oil in ½ and 1 gr. capsules has also been tried. Better than this, however, are the ethyl esters. MacDonald and Dean in the Philippines use "Moogrol," beginning with 1 c.c. and increasing this by 1 c.c. every third injection until 6 c.c. is reached. The injections are given once a week intravenously. Another way is to combine the ethyl esters with creosote, camphorated or olive oil, and give this hypodermically once a week. Beginning with a dose of ½ c.c. this is increased by ½ c.c. each time, till 7 c.c. at a dose is reached. Iodochin—calcium iodo-ricinoleate—is also recommended. grs. ii-j-v, or more, t.i.d. Rogers tried the sodium salt of gynocardic acid, sodium gynocardate, and claimed good results from its use. It can be put up in 3 gr. tablets, and three or four of these are given t.i.d. by the mouth. Later he suggested giving sodium morrhuate as well, and his results from this method have been very good in several cases. The sodium morrhuate

injections are given intravenously, and are best administered in a 3 per cent. solution, ampoules of fresh solution being used each time. The initial dose is $\frac{1}{2}$ c.c., increasing this by $\frac{1}{2}$ c.c. each time till 3 c.c. has been attained. They are given once or twice weekly. The newest of these chaulmoogra oil derivatives is a preparation by Burroughs, Wellcome & Co. called "Alepol" (sodium hydnocarpate), a sodium salt of selected fractions of the fatty acids of *Hydnocarpus Wightiana* oil. This can be given in a 3 per cent. solution subcutaneously and intramuscularly without pain, and in a 1 per cent. solution intravenously. The dose is from 1 to 5 c.c. It must be clearly borne in mind that chaulmoogra oil and its different extractives are only palliatives in the treatment of leprosy. They are not specifics, and the extravagant and exaggerated claims lately put forward for them—in the lay press—are fallacious and do not represent the true state of affairs. Injections of Deycke's nastin, combined with benzoyl chloride, had a vogue for a time, but they have lately fallen out of favour. For skin lesions, Unna recommends ichthyol, pyrogallie acid, resorcin and chrysarobin. Radio-therapy and electricity have also been tried.

G. CARMICHAEL LOW.

GLANDERS

Definition.—An infectious disease, occurring not infrequently in the horse and in the ass, occasionally transmitted to man, and characterised by the formation of granulomatous nodules in the nose (glanders), and in the subcutaneous tissues (farcy).

Ætiology.—The *bacillus of glanders*, or *Bacillus mallei*, is a short rod, straight or slightly bent, of 3 to 4 μ in length by 0.5 to 0.75 μ in thickness. It is non-motile, and possesses no flagella, nor does it form spores.

The bacillus stains somewhat faintly with the usual aniline dyes, so that a mordant, such as carbolie acid, is usually employed, but even when deeply stained there is a tendency to decolorise rapidly. The staining is markedly irregular, this irregularity being a diagnostically helpful point. It is Gram-negative.

Pathology.—The disease chiefly affects horses, mules and asses the latter being the most susceptible. Horned cattle are immune, but goats and sheep are occasionally infected.

In the horse, infection may take place through any abrasion of the skin, but most frequently through abrasion of the nasal mucous membrane from infected water-troughs or feeding-mangers. The infection may be acute or chronic. In the acute form (glanders proper) there is fever and prostration, and in two or three days there occurs ulceration of the nasal mucosa with a sero-purulent discharge, leading on to involvement of the lungs, and death within a few weeks. In the chronic form—farcy—there is involvement of the lymphatic system associated with the original site of entry. The lymph vessels become enlarged—farcy pipes—and irregular thickenings—farcy buds—occur, which may soften and suppurate.

The disease may be latent, and can then only be diagnosed by the "mal-

lein" test. In the human being the infection is generally derived directly from the horse, and is therefore usually confined to those in close connection with horses; but the disease has been contracted in the laboratory.

The toxin of *B. mallei* or mallein is an endotoxin, being derived from the bacterial bodies, in which respect it differs markedly from the toxins of tetanus and diphtheria bacilli. One of its chief characteristics is its resistance, it being capable of withstanding temperatures of 120° C. and prolonged storage with but little loss of strength. It is prepared by growing cultures in glycerin broth for 3 or 4 weeks, and sterilising these by boiling or autoclaving at 115° C. The cultures are then allowed to stand, and the supernatant fluid being decanted off, this is then filtered through a Chamberland filter. The resultant filtrate, to which one-half of 1 per cent. of carbolic acid is added, constitutes *mallein*. It contains the soluble portions of the bacteria, and substances from the altered medium, and is a similar product to tuberculin. It is used in doses of 1 c.c. to detect a glanders infection in the horse. As the reaction in a "glandered" animal is severe, both locally and constitutionally, it is unsuitable for use in man.

Forms of the disease.—Both glanders and farcy have been known to occur in man in acute and in chronic forms. All forms are rare.

Symptoms.—1. *Acute glanders.*—The incubation period varies, but is in most cases 4 days. At the site of infection in the nose there occurs an inflammatory swelling surrounded by œdema and lymphangitis, with a papular eruption soon becoming pustular. In a few days other and similar swellings appear, which soften and ulcerate, so that the mucosa of the nose becomes generally infected, leading to profuse muco-purulent discharge. The whole nose swells, it may be very considerably. The ulceration extends deeply so as to involve the cartilage and bone. The cervical lymph glands are usually enlarged and may soften, forming abscesses. Constitutional symptoms are present by this time, and death, usually with pneumonia, occurs about the middle of the second week.

2. *Chronic glanders.*—This form resembles closely the disease as seen in the horse. There is a chronic profuse coryza, associated with widely scattered muscular and subcutaneous nodules. Unless the nature of the disease is suspected, it may go undiagnosed for some time.

3. *Acute farcy* is the form of the disease resulting from accidental inoculation of the skin. A local lesion of a highly inflammatory kind leads quickly to a spreading zone of lymphangitis, subcutaneous nodules (farcy buds) appearing in the track of the infection, softening and forming abscesses. The patient becomes severely ill, with symptoms of a general infection, and the course of the disease is of much the same duration as in acute glanders.

4. *Chronic farcy* only differs from acute in that the "buds" are associated with much less inflammatory reaction, the constitutional symptoms are much less severe, and the course of the disease is much longer. A few of the cases have extended over 12 months.

Diagnosis.—Acute glanders has been mistaken for small-pox, owing to the likeness of the papulo-pustular eruption to the specific eruption of this disease. The chronic forms are at times mistaken for the other infective granulomata (syphilis, tuberculosis and actinomycosis). Exact diagnosis turns upon bacteriological methods, direct or indirect.

The *bacteriological diagnosis* in man may be simple if a superficial swelling exists which may be opened. Direct cultures may be made therefrom, preferably on potato, and a rapid diagnosis made. It may be, however, that weeks elapse before such an opportunity occurs, or before some deeply situated swelling calls for operative interference. In such cases serum reactions, such as the complement deviation test and the sedimentation test, are indicated, and in a case watched by one of the authors the diagnosis was made by the opsonic test several weeks before the bacilli were cultivated from the tissues.

If material containing *B. mallei* be injected intraperitoneally into a male guinea-pig, tumefaction and suppuration occur in two or three days in the tunica vaginalis, and the bacilli can be recovered therefrom.

Treatment.—The site of inoculation, if obvious, should be excised, and the underlying tissues should be treated drastically by strong antiseptics. All abscesses should be opened promptly and efficiently drained. The general symptoms are met by treatment similar to that given in any septicæmia. The only form of immune therapy promising any help is the use of vaccine, of which doses of 5, 10 and 25 million bacilli should be given at intervals of 2 to 3 days. If no undesirable reactions occur the dose should be cautiously increased.

THOMAS HORDER.
JOHN MATTHEWS.

MELIOIDOSIS

Definition.—A disease resembling glanders, occurring in the Federated Malay States and Burma.

Ætiology.—The disease is due to a bacillus, viz., the *Bacillus whitmori*, an organism closely resembling the glanders bacillus, *B. mallei*.

Symptoms.—Stanton describes, in acute cases, diarrhœa, with collapse resembling that of cholera, this being followed by septicæmic symptoms with pulmonary lesions like tuberculosis. In chronic cases there are lesions of the nature of abscesses in the skin and subcutaneous tissues, the spleen, liver and lungs.

Treatment.—Autogenous vaccines have been tried, otherwise there is no specific treatment.

G. CARMICHAEL LOW.

INFLUENZA

Definition.—An acute infectious disease, existing in pandemic and epidemic form, with sporadic outbreaks. The nature of the causative virus is not yet established, but *Bacillus influenzae* (Pfeiffer) is found in very close association with the morbid lesions, especially those of the respiratory system, which the disease is specially prone to attack.

Ætiology.—Are the protean features of disease which are at present included in our conception of influenza all manifestations of the same *matæries morbi*? Are there influenzas rather than influenza? What causative factors determine the pandemics of the disease during which the case-incidence

risers so rapidly and so enormously? What is the association between benign influenzal catarrhs of endemic and sporadic occurrence and the pandemics which decimate whole races of mankind? These are questions which have baffled epidemiologists and bacteriologists for many years, nor have the exceptional opportunities for observation and research afforded by the pandemic of 1918-19 served to answer them.

We are ignorant of the reasons why a state of relative quiescence in regard to the incidence of the disease—scattered sporadic cases and mild epidemics—suddenly blazes up into a devastating pandemic. We know that when this conflagration arrives the disease becomes very highly infectious in character, that its virulence is enormously increased and that the usual close association with catarrhs and seasons and latitudes and lowered general resistance is no longer observed. Age gives no security at such times; witness both the high case-incidence and high case-mortality in young adults during the pandemic of 1918-19.

A previous attack of the disease gives little or no protection; according to some authorities the reverse is the case.

In the matter of its relation to other catarrhal states the absence of definite criteria makes it impossible to be precise in diagnosis. It is only in the presence of a severe and widespread outbreak that the guide of probability is of assistance in this respect.

By some the claims made on behalf of Pfeiffer's bacillus, that it is the essential virus of the disease, are considered to be overwhelming. By others this micro-organism is regarded as being at the most the commonest secondary invader of the infected tissues. The primary microbic factor is thought by the writer and others to be of the filter-passing variety; indeed, it is probable that a minute organism quite recently isolated by American workers, using the Noguchi method of culture, is the actual causative virus. Next to Pfeiffer's bacillus the micro-organisms most commonly found in association with the disease are streptococci of the hæmolytic kind, pneumococci, *M. catarrhalis* and *Staphylococcus aureus*. It seems certain that many of the most serious and fatal cases owe their lethal character to virulent streptococci.

Pfeiffer's bacillus occurs in cases of disease quite other than clinical influenza—infective endocarditis, sinusitis and meningitis. And if we add to these, catarrhal processes which, again, either from their chronicity or other features, differ markedly from epidemic influenza, it is clear that this micro-organism, if it really be the causative microbic agent in the last-named disease, must at times undergo great variations in virulence. The bacillus is of very small size, is Gram-negative in staining reaction, grows with difficulty on ordinary media and has low vitality outside the human body. A special feature seen in regard to it is the fact that, when present in acute cases of influenza, it usually occurs in enormous numbers in the infected tissues and their secretions.

Symptoms.—So far as can be judged the incubation period is, with considerable constancy, something from 24 to 48 hours. A marked feature of the disease is the abruptness of the onset. So abrupt is it at times that the victim is stricken down, as it were, in the street, and, from being quite well he is, within a few hours, prostrated and already suffering the maximum discomforts of the disease. The temperature rises rapidly; there is often a rigor. The chief symptoms are racking headache, intolerable aching pains

in the loins and limbs, dryness and irritable redness of the mouth and fauces, and a distressing cough. An erythematous rash is not uncommon.

Although the symptoms are protean, it is customary to describe certain types of case that are frequently met with, dependent largely upon the particular tissues and functions which suffer the chief results of the infection.

1. *The febrile type.*—In this variety of the disease the chief features are pyrexia, with associated malaise, headache, pains in the back and limbs and a moderate degree of catarrh of the upper air-passages. In many cases this type differs only from the "common cold" in its more abrupt onset, its higher degree of pyrexia, its disproportionately severe prostration and its relatively "dry" form of catarrh. The eyeballs are often painful, with some conjunctivitis, and the fauces are often red and slightly œdematous. Cough is often present, with few or no associated pulmonary signs. The pyrexia lasts for a variable time, usually 4 to 6 days; it is unusual to see the fever prolonged past the eighth day without some focal complication, generally pulmonary. Defervescence is quite frequently by crisis, but this is by no means the rule.

2. *The respiratory type.*—This is the form of the disease which is most prevalent in pandemics, and, when severe, it is the form to which the mortality is chiefly due. Somewhere about the fourth day of the disease it becomes obvious that the catarrhal process is growing troublesome, with more definite involvement of the larynx, trachea and bronchial tract. In many cases the temperature falls about the third or fourth day, to rise again concurrently with a definite exacerbation and extension of the catarrh. The respiratory involvement does not tend to remain localised as a bronchitis, but involves the lung tissue, leading to a bronchiolitis and, in many cases, an alveolitis also. Then ensue the signs of acute pulmonary congestion which are so characteristic of the disease, and cause so much anxiety for fear of untoward developments. The respiratory manifestations of influenza infection extend from laryngitis and tracheitis through bronchitis to lobular and lobar pneumonia and pleurisy, both "dry" and with serous or purulent effusion. But the dominant feature, rarely absent in any really severe case, is a condition of capillary bronchitis with intense pulmonary congestion. This may be unilateral or bilateral, is more often basal than apical, but is not seldom universal. The physical signs are copious fine râles (crepitation), with impaired vesicular sound, and, less often, impaired percussion tone. This condition may well be termed the essential lesion of the disease, for even when actual consolidation of the lung is present, this is quite often an incident by comparison, and if the patient dies, he dies with the consolidation rather than of it.

Cough is usually a very troublesome symptom in this type of the disease, and is often quite independent of the need to expectorate. The sputa vary considerably. They may be quite absent, even in cases where there is widespread lung congestion. When present they are generally of a kind that corresponds with the nature of the chief lesion, whether tracheitis, bronchitis or pneumonia. Two special kinds of sputa are very typical of influenza, and they are seen frequently during epidemics. (a) Bright, pink, frothy mucus, sometimes produced in large amount, it may be as much as a pint in 24 hours. This rose-red mucus results from acute inflammatory œdema of the lung. It may be expelled involuntarily during cough and sometimes

it spurts from the nostrils. (b) Tenacious mucus, less viscid than in lobar pneumonia, and more copious, differing also in colour which is of several hues—red, brown, saffron, and various shades of green, all of these being occasionally present at the same time. Seen in a white earthenware vessel these sputa are very striking and in a high degree diagnostic.

3. *The malignant type*.—This severe and very fatal form is almost confined to pandemic or to epidemic periods. The patient is gravely ill from the onset, or soon after, with intensely toxic symptoms, cyanosis of a peculiar character ("heliotrope cyanosis") and rapid development of heart failure before focal manifestations have time to show themselves—unless it be the presence of fine copious râles of the kind referred to in (2). The duration of this type of case varies from 48 hours up to a week, and no measures of treatment, however prompt, serve to avert the almost certain issue.

4. *The gastro-intestinal type*.—More strictly, perhaps, gastric and intestinal types. These types are less common in pandemics and epidemics than in small endemics and in sporadic cases. The gastric cases are quite common, and some of the milder endemics seem to "breed true" to a remarkable degree in this respect, leading to a very constant clinical picture of an illness with acute, even abrupt, onset, vomiting, marked anorexia, epigastric and umbilical tenderness and general prostration. Considerable difficulty often arises in diagnosis (see p. 126), even when there are several cases of a similar kind prevalent.

Jaundice of the catarrhal kind is not very uncommon as a complication. Some of the intestinal cases give no less difficulty, and when severe the likeness to typhoid fever is sometimes very close indeed. Tympanites, diarrhoea and enterorrhagia, associated with continued high fever and a leucopenia, may deceive the very elect.

5. *A nervous type* has been described, but it is perhaps more correct to say that a variety of nerve symptoms may arise both during and after the acute infection, rather than that a recognisable clinical picture is produced (see p. 126).

Complications and Sequelæ.—These are both numerous and important. Indeed, if we except the malignant cases and the very severe respiratory cases occurring during pan- and epidemic periods, it may be said that the importance of the disease lies more in its complications, and perhaps still more in its sequelæ, than in the stage of infection proper. For convenience these disabilities may be grouped as follows:

1. *Respiratory*.—The main extensions of the catarrhal process have been already referred to, as also has the occurrence of pleurisy. Sinusitis may be mentioned here; it is both common and troublesome. Otitis media also occurs. Asthma sometimes appears for the first time in a patient's life after influenza, and the age of the sufferer may be much more advanced than is usual with asthma generally. Pulmonary tuberculosis not seldom shows itself also for the first time in the same association. The most frequent sequel of all, however, is the maintenance of a state of chronic congestion or bronchiolitis at one base or both bases of the lung. This condition may persist for years, ebbing and flowing with the seasons and with the occurrence of intercurrent catarrhal infections.

2. *Circulatory*.—Perhaps the most serious complication and sequel is referable to the heart. Some degree of dilatation is very common during a

severe attack of the respiratory type, and this condition is apt to prolong convalescence in a very tedious fashion. But a much more common form of heart disability is that which arises insidiously after the patient begins to resume his usual routine of life. He is the subject of palpitation, præcordial distress and a sense of undue fatigue with slight effort. In women this state of things is complicated often by nervous symptoms, and attacks of breathlessness and a sense of impending collapse are quite common. As there is frequently in addition a considerable degree of true nervous prostration with mental depression it becomes exceedingly difficult to decide to what extent the heart is really affected. Physical signs in these cases are wholly inadequate; quite often they are absent altogether. Although, with care and encouragement, many of these cases get quite well after a time, a large number unfortunately become more or less permanent "heart invalids." It is not clear what is the exact pathology of the "influenzal heart," but it is perhaps near the truth to consider it in the main a toxic myocarditis; though to what degree it is the nervous mechanism, and to what degree the heart muscle, that suffers we cannot say.

Vasomotor troubles are not uncommon and often complicate the heart condition. Phlebitis may occur.

3. *Nervous*.—The most common complication is the intense depression from which the patients so frequently suffer. In a few cases this leads to actual mental instability and, in fewer still, to suicide. The depression may continue for a long time after the acute illness is over. So common a symptom is it that patients themselves often consider the nature of a recent febrile illness to be definitely established as influenza because of this resultant depression. And they are probably in most cases correct. The headache, which is another very constant accompaniment of the illness, may be so severe as to raise the question of meningitis; it quite commonly leads to some delirium in patients whose nervous system is, in health, none too stable.

A true meningitis occurs now and again with *B. Pfeiffer* in the cerebro-spinal fluid and a clinical picture that is unequivocal. Encephalitis and myelitis are described, but here, again, the diagnosis—from epidemic encephalitis—must always be a difficult matter.

Many other nerve conditions are described by authors. Perhaps neuritis, of both single and multiple types, is the most common. The writer has seen a condition indistinguishable from paralysis agitans follow a severe attack, which ended in complete recovery after several months.

Diagnosis.—During pan- and epi-demics the diagnosis is, as a rule, not difficult, especially when the case is very severe. "Filming" the sputa in a case of the respiratory type is a most valuable aid to diagnosis. If the highly characteristic condition of bronchiolitis with copious fine râles referred to on p. 124 be present in a febrile illness with nerve prostration and general toxæmia, the diagnosis is fairly certain.

The gastric and intestinal cases, and especially the latter, present more difficulty than do the respiratory cases. The gastric cases resemble food-poisoning not a little, and appendicitis may require careful consideration in patients with abdominal tenderness, pain and vomiting, of acute onset. From typhoid fever a severe intestinal case with hæmorrhage and enlarged spleen can only be distinguished by absence of agglutination and negative blood culture. A leucopenia is present in both diseases.

The diagnosis of milder cases of influenza, if occurring in sporadic fashion, is frequently a frank admission that it is well to give the patient and his friends a label to his disease. There are so many causes of an acute febrile illness with malaise and slight catarrh that exact diagnosis may not be possible.

A word of warning is perhaps necessary in respect of diseases known to be prevalent coincidentally with outbreaks of influenza. Thus, true pneumococcus pneumonia, whether lobular or lobar, is not infrequently called influenza when this latter disease is epidemic. Of greater importance is the fact that waves of incidence of influenza and poliomyelitis and encephalitis sometimes concur. If the practitioner's attention is bent only upon the former disease he is apt to put down to it certain serious nerve lesions that really belong to the latter.

Prophylaxis.—As we do not know the factors leading to the production of influenza epidemics we do not know how to prevent them. When they arrive we can, to some extent, control them by efficient quarantine, by early diagnosis and notification and by a proper system of hospitalisation, adequate to the peculiar features presented by the disease. In regard to individual prophylaxis it was formerly held that to keep generally "fit" was a good protection against infection. But recent experience does not confirm this view: influenza attacked the strong as well as the weak; indeed, the robust young adult fell a victim by preference, though this may have been partly because he was more open to infection by virtue of the conditions of his life. The age-mortality as well as the age-morbidity during the 1918-19 pandemic seemed to make it clear that some method of specific immunisation is essential before we can hope to protect against infection. But in the absence of exact knowledge of the causative agent, specific prophylaxis of a convincing kind is scarcely practicable. The available vaccines for protective inoculation perhaps aim as much at raising resistance against the secondary infections which are frequently so harmful as against the primary invader. Regarded in this light they are rational; but it is still too soon to give a proper judgment upon the question of their therapeutic efficacy.

Treatment.—1. GENERAL MEASURES.—With the onset of symptoms the patient is put to bed and is kept there until the temperature has reached normal and has remained there for at least 24 hours. He is only allowed up if examination of the heart and lungs, and a review of his general condition, reveal nothing abnormal. If the attack has been more than a mild one, it is well to induce the patient to remain in bed for 4 days after the temperature is normal, so as to be on the safe side, because relapses are common, and are often more dangerous than the original attack. This rule of practice should certainly have no exception in the case of patients over 50 years of age.

The largest available room is chosen and the bed is placed well away from the walls. Blinds, curtains and screens are dispensed with, and the windows are kept open day and night. The room temperature is kept as near to 60° F. as possible. If the ideal of free ventilation with warmth cannot be secured, then warmth must be sacrificed rather than ventilation. Neglect of fresh air not only seriously prejudices recovery in the event of pulmonary complications, it undoubtedly tends much to induce them. It is probably the most important point in the treatment of all cases. The bedclothes are adjusted to the patient's temperature, only using sheets and blankets.

The diet is confined to hot fluids, given frequently in all severe cases, but easily digested solids are allowed if the stomach tolerates them; efforts at "feeding up" the patient are to be deprecated. Unless the patient is elderly, alcohol is not needed in the early stages of the disease when there are no complications. The bowels are made to act thoroughly by a double dose of the patient's customary aperient. If he has none, he is given 1-grain doses of calomel every hour for 4 doses, and this is followed by a saline draught. The patient is sponged all over with warm water twice daily.

2. **Drugs.**—There is probably no drug which acts as a specific. Aspirin and Dover's powder in 10-grain doses may be given together as early as possible and may be repeated once or twice after 6 or 8 hours. This may be followed by a simple diaphoretic mixture.

3. **TREATMENT OF SYMPTOMS.**—If the headache is severe, phenacetin gr. x with caffeine gr. ij, may be given 4-hourly for 4 doses. If the stomach gives trouble and the tongue is foul, sod. bicarb. and sod. sulphocarb., of each gr. x, with glyc. acid. carbol. ℥x, may be given 6-hourly with the feeds, well diluted. For vomiting, all feeds are reduced to a minimum, or omitted entirely for 48 hours, giving sips of hot water only, with minim doses of tinct. iod. in 1 dr. of water hourly for 6 or 8 doses, injecting 1 pint of normal saline into the bowel two or three times during the period of starvation.

Distressing and persistent cough is often the most difficult problem. Local applications to the chest are often of service. If the origin of the cough is irritability of the upper-air passages inhalations of tinct. benzoini co. 4 parts, with menthol or eucalyptus 1 part, are useful. Failing this a spray, containing chloretone and menthol, 2 per cent. of each in liquid paraffin, may be used to the nose and throat. In the "essential cough" of the disease, syr. cocillanæ co., syr. codeinæ and tinct. terp-heroin co. are of some value. In intractable cases relief may follow syr. chloral ʒss, ammon. brom. grs. x, with ext. glycyrrhiz. liq. ℥xx, etc., in 4-hourly doses for 4 doses.

Insomnia calls for a general review of the whole programme—ventilation, control of pyrexia, posture, food, stimulants, etc. Failing attention to these things, a sedative draught of ammon. brom. grs. xx and tinct. valerian. ℥xx may be tried. If not successful, ʒij-doses of paraldehyde, with tinct. quillaia and tinct. aurantii to cover its unpleasant taste. Failing this, again, chloral and bromide may be given, since drugs of the veronal group are better avoided.

4. **TREATMENT OF MORE SEVERE CASES AND OF COMPLICATIONS.**—(a) *Intensely toxic cases, with hyperpyrexia.*—Attention to good ventilation should be redoubled. The thermometer and not the patient's sensations must be the guide to the amount of bedclothes. "Cradling" is often very useful, as also is tepid or spirit sponging. In cases in which the temperature is even then resistant, the cold pack should be used and repeated if necessary. Febrifuge drugs are to be avoided in such cases. Stimulants are now advisable to counteract circulatory failure.

(b) *Pulmonary cases.*—Linseed and mustard poultices are of service here, or antiphlogistin, applying these to the most "congested" parts. Volatile stimulants, sedative expectorants and diaphoretics are the most useful drugs: sp. ætheris co., the iodides in small amounts, bromide and chloride of ammonium, tinct. senegæ, tinct. belladonnæ and liq. ammon. acetatis. Ammon. carb. should only be used where sputa are present, and large doses

are of doubtful value at any time. Oxygen passed through warm alcohol is useful in all severe cases with cyanosis.

(c) *Heart failure*, to be estimated more by the general state of the patient (facies, cyanosis, dyspnoea, delirium, posture) than by pulse-frequency or physical signs, is met by alcohol, strychnine injections, camphor in oil (3 grains in 15 minims) intramuscularly, and, as a measure supplementary to these, *strophanthin* $\frac{1}{10}$ grain in 20 minims of sterile saline solution, injected slowly into a vein of the arm and repeated, if indications are still present, in 8 or 12 hours.

(d) The *post-febrile stage*, often a stage of cardiac and nervous exhaustion in severe cases, requires some caution. Strict recumbency should be enjoined, with careful feeding, stimulants and tonics.

5. **IMMUNE THERAPY.**—There is even greater diversity of opinion as to the value of specific measures of treatment for the disease than there is for prophylaxis. If it be decided to adopt such measures it seems clear that they should be tried as early as possible after the onset. But this means that autogenous vaccines cannot be employed. The stock formulæ recommended for use vary considerably, but all of them are based upon the principle of “mixed” infection by *B. pfeiffer*, streptococcus, pneumococcus and *M. catarrhalis*. Seeing that so many of the fatal cases appear to be so because of virulent streptococcus toxæmia some authorities give anti-streptococcus serum early in the disease in all bad cases, and the writer favours this practice. Liberal doses should be given, such as 100 c.c. intravenously in very severe cases, and 25 c.c. repeated two or three times at intervals of 12 hours subcutaneously in cases in which the infection seems less intense.

6. Many experimental methods of treatment were exploited during the pandemic 1918-19, including a large range of antiseptics by the intravenous route. But no remedy emerged from all the trials thus undertaken with sufficient credit to merit a reference here.

THOMAS HORDER.

WHOOPIING-COUGH

Synonym.—Pertussis.

Definition.—An acute specific disease of high infectivity, characterised by catarrh of the respiratory tract, combined with periodically recurring laryngeal spasms of distinctive type and other signs of nervous disturbance.

Ætiology.—Whooping-cough is mainly a disease of temperate climates, being rarer and less severe in hot countries. Spring and autumn are the seasons of its maximum prevalence, and also of its greatest mortality, chiefly owing to respiratory complications; but the disease may also occur in the warmer months, even in epidemic form. It is more prevalent in cities and industrial centres than in the population of rural districts. Persons of all ages, if unprotected by a previous attack, are susceptible to the infection; but whooping-cough is essentially a disease of childhood, and, moreover, shows a stronger tendency to attack young infants than does any other specific disease. Most attacks occur between the ages of 1 and 10 years. Infants under the age of 12 months often succumb. The *fœtus in utero* has been known to contract the infection from its mother, and to show the characteristic

symptoms soon after birth. As regards sex, more females than males are attacked. The frequency with which whooping-cough follows an attack of measles is noteworthy. A second attack of whooping-cough is very rare.

Infectivity is greatest during the catarrhal and early paroxysmal stages; but its exact duration is a matter of dispute. On rare occasions convalescents are said to have acted as carriers of the disease.

The infection is usually direct, being conveyed by the mucous droplets in the expectoration. Since the virus can resist drying for several weeks the disease may also be conveyed by fomites, but this is uncommon. One attack almost invariably confers lifelong immunity.

Bacteriology.—Of the various organisms which have been alleged to be the causal agents, the bacillus of Bordet and Gengou has the strongest claims to acceptance. This is a minute, slender rod closely allied to the bacilli of the influenza group. It is Gram-negative, and only flourishes on artificial media which contain blood or serum. It grows best at blood heat. Cultures are most easily obtained from the small pellets of viscid mucus which are expectorated at the end of a paroxysm of coughing. The blood of convalescents agglutinates the bacilli.

There are no post-mortem appearances which are distinctive, the changes found after death being due to complications. Of these, congestion of the air-passages and broncho-pneumonia are the most common, and are accompanied by general acute vesicular emphysema. The tracheo-bronchial lymph glands are usually soft and swollen.

The paroxysmal cough is attributed to the action of the virus in producing hyperæsthesia of the respiratory mucous membrane and to heightened excitability of the vagus nerve, but toxic influence on the nerve centres is probably widespread.

Symptoms.—The incubation period is difficult to fix with accuracy, owing to the insidious nature of the onset and the delayed appearance of the characteristic whoop, but it is most probably 13 to 15 days. Extremes of 4 days and 3 weeks have been claimed. During a typical attack three stages may be recognised—the catarrhal, the paroxysmal, and the convalescent.

The catarrhal stage lasts from seven days to a fortnight—it is febrile, and in many ways resembles a somewhat severe respiratory catarrh; but the cough is more troublesome and generally accompanied by some sonorous and sibilant rhonchi. Recognition of the disease at this stage is difficult unless the patient is known to have been exposed to the infection. Suggestive signs towards the end of the period are a tendency of the cough to assume a paroxysmal character, with greater severity at night and occasional culmination in vomiting.

When the paroxysmal stage is reached the disease is unmistakable. Fever will usually have subsided; but the cough occurs in paroxysmal bouts, often spontaneous, but frequently the result of external stimuli, such as excitement, draughts, the ingestion of food or examination of the throat. Several paroxysms may occur in quick succession with longer or shorter intervening periods of freedom. The victim knows when the cough is impending, and may for a time attempt to suppress it. If lying in bed a child will sit up, if about he may run to his mother or nurse. A brief, deep inspiration is followed by a rapid succession of short coughs, with open mouth and protruded tongue,

which are continued until the chest is almost emptied of air. The face becomes congested or livid, the superficial veins are engorged, and the eyes fill with tears. The eyeballs protrude, the skin is bathed in sweat, and suffocation appears imminent; but relief is suddenly afforded by relaxation of the laryngeal spasm and the occurrence of the whoop, a long-drawn crowing inspiration, which refills the lungs with air. The paroxysm then recurs, and may be repeated several times, leaving the child perspiring and exhausted. The bout often terminates with the discharge from the air-passages of a pellet of viscid, transparent mucus. A quantity of thin sticky secretion, which is sometimes blood-stained, may also flow from the mouth and nose. During the fits of coughing, which often last for 2 or 3 minutes, the child may faint or become convulsed and insensible. The contents of the stomach are often ejected, and the urine may be voided; in some instances incontinence of fæces occurs. Epistaxis is not uncommon in the more severe attacks. Subconjunctival hæmorrhage may occur, and petechiæ appear in the skin of the eyelids and other parts. Rarely the membrana tympani is ruptured, and blood escapes from the ear. In infants asphyxia may occur and call for artificial respiration.

In the early paroxysmal stage the cough is only occasional, but its frequency soon increases, and in a case of moderate severity from 15 to 20 paroxysms occur in the 24 hours; in some attacks, however, they are much more numerous. They are characteristically most frequent and most severe at night.

Physical examination of the chest at this stage will still reveal signs of diffuse bronchitis; but this is now accompanied by a greater or less degree of acute emphysema and a moderate degree of abdominal distension is not uncommon. The forcible protrusion of the tongue over the lower incisor teeth often produces a shallow ulcer on the frænum linguæ.

The duration of the paroxysmal stage is from 3 to 10 weeks, and after this convalescence begins. Whooping-cough is more prolonged in winter than in summer, and its duration is increased if complications ensue. After the whoop has ceased a fresh attack of respiratory catarrh may cause it to reappear; but this should not properly be regarded as a relapse, and does not render the patient again infectious.

The blood shows a leucocytosis even in the early catarrhal stage. Both polymorphonuclear cells and lymphocytes share in the increase; but the lymphocytes are increased out of proportion to the other cells and may constitute 66 per cent. of the total count; myelocytes may also make their appearance. The leucocytosis is said to be increased after each paroxysm of coughing, and the highest counts to be found during convulsions. The supervention of pneumonia increases the polymorphonuclear cells.

Course.—Attacks vary in their severity and duration. Mild infections may run their whole course in a week or two, whilst severe ones may last several months. As mentioned above, the number of paroxysms in 24 hours is some measure of the severity. The danger of supervention of complications is broadly proportional to the severity of the attack. When whooping-cough occurs in the adult the whoop is much less conspicuous, and may be entirely absent, but the cough retains its paroxysmal character and nocturnal severity. In infants, too, the whoop may be very imperfectly developed.

Complications.—These belong mainly to the paroxysmal stage of the

disease—they are partly mechanical and partly inflammatory in nature. The most serious are excessive vomiting, broncho-pneumonia and convulsions.

When the paroxysms of coughing are frequent and severe, excessive vomiting may lead to great emaciation and exhaustion. Diarrhœa and ileocolitis may also occur, mainly in younger children, and during the summer months.

Pulmonary complications are frequent, and are more common during the winter. A mild general bronchitis with general, but temporary, acute emphysema is the rule, and is of but little moment. Capillary bronchitis or broncho-pneumonia, with patchy pulmonary collapse, is much more serious. It usually occurs at the height of the paroxysmal stage, and is responsible for two-thirds of the deaths. Interstitial emphysema of the lung may result from rupture of an air cell during coughing, but is only likely to be recognised when it overflows into the root of the neck and the connective tissue of the chest wall. Bronchiolectasis is an occasional sequel of the disease.

Convulsions may occur in infants and younger children, and prolonged attacks of glottic spasm may induce asphyxial fits. Aphasia, coma, hemiplegia, paralysis of ocular nerves and defects of sight, hearing, and intelligence sometimes supervene. Bulbar paralysis and polyneuritis have also been described. Cerebral congestion and meningeal hæmorrhages account for some of these complications; others, such as polyneuritis, are probably due to toxæmia. Defect in vision is sometimes found to be due to retinal hæmorrhage or detachment.

The strain of the recurrent paroxysms of coughing may induce dilatation of the right ventricle of the heart, subconjunctival hæmorrhages, epistaxis, bleeding from the mouth or ears, hæmoptysis, and hæmorrhage on the surface or less commonly in the substance of the brain. Other results are the appearances of herniæ and prolapse of the rectum.

True nephritis is rare, but albuminuria may appear. Glycosuria is occasionally seen.

An unhealthy condition of the naso-pharynx may persist after the cough has subsided, and no other disease except measles has such a bad reputation as whooping-cough as a forerunner of tuberculous manifestations.

Diagnosis.—In the absence of known exposure to infection, diagnosis may be impossible until the whoop is heard; but the significance of a paroxysmal cough, worse at night and terminating in vomiting, should not be overlooked. The disproportion between the violence of the cough and the accompanying physical signs in the chest is also noteworthy. When broncho-pneumonia does supervene the whoop may cease. In infants the cough may be paroxysmal and asphyxiating, but the whoop not developed; in such cases, as also in adults when the whoop is absent, the diagnosis may be cleared up by the occurrence of infection in contacts.

The spasmodic cough of bronchial gland irritation and of adenoids is apt to be paroxysmal, but the whoop is wanting. The same observation applies to the obstinately recurrent coughs of influenza and bronchiolectasis. In children, laryngeal inflammation of catarrhal or of syphilitic origin may induce paroxysms of cough and laryngeal spasms, but the tone of the cough at once indicates its laryngeal origin. Conversely, whooping-cough in its early

stages, if accompanied by an unusual amount of laryngeal catarrh, may be confused with the laryngitis of measles or of diphtheria.

In the catarrhal stage the malaise, cough, pyrexia and slight fullness of the abdomen with perhaps some irregularity of the bowels, may arouse unfounded suspicions of early general tuberculosis.

The leucocytosis of whooping-cough, which is considerable in the early stages, may prove of assistance in the early diagnosis of the disease. An authentic history of a previous attack puts whooping-cough for all practical purposes out of court, second attacks being excessively rare.

The presence of the sublingual ulcer is only to be expected after the incisors have appeared. Occasionally it is seen in other conditions of persistent cough.

Prognosis.—Whooping-cough is a much more serious malady among the children of the poor, and in those suffering from malnutrition, rickets, tuberculosis, or a predisposition to chest troubles, than it is to healthy children in comfortable circumstances. Apart from this, age constitutes the most important prognostic factor. Infants and children under 3 years of age suffer a considerable mortality, which for the first 12 months of life is estimated at 25 per cent. The mortality decreases rapidly after the third year, and after 10 years of age is insignificant. Hence it is found that more than two-thirds of the deaths from whooping-cough occur during the first year of life, the younger the infant the worse being the outlook. Of complications, broncho-pneumonia causes most of the deaths, occurring chiefly in the winter months. In the summer, ileo-colitis comes into prominence.

Convulsions, especially if repeated, are of grave omen. Death at times occurs suddenly from asphyxia due to sustained laryngeal spasm, or from heart failure or intracranial hæmorrhage. When tuberculous lesions are present these may be stirred into activity by the infection, and especial care is necessary.

A cautious prognosis should be given with regard to paralytic sequels, since in a number of cases these prove permanent.

Treatment.—Isolation should be enforced, but free ventilation with abundance of fresh air is desirable, and gives better results than confinement in a close room and the inhalation of medicated vapours. In the absence of fever, patients may be allowed up and out as much as possible, provided isolation can be maintained. In suitable weather continuous open-air treatment may be adopted even for those patients who are confined to their beds. A light binder should support the abdomen, and the clothing be loose and not too heavy. When lung complications are present a jacket of gauze tissue should be worn. The diet should be light and digestible, excess of starchy and saccharine food being avoided. When vomiting is persistent it is a good rule to administer food in small quantities immediately after the paroxysms of coughing. Overloading the stomach may aggravate the cough. A diet of milk or whey may be necessary in some instances. Rectal feeding is very unsatisfactory. The chest may be rubbed as a routine with some stimulating liniment.

As regards drugs, there is no specific, although quinine or euquinine in large doses have been regarded as such. During the catarrhal stage simple expectorant mixtures are sufficient, and later the paroxysms may be mo

by such sedatives as bromide, belladonna, antipyrine, bromoform, chloral, paregoric and heroin, all of which have their advocates. Perhaps belladonna in increasing doses and antipyrine are the most generally useful; the latter may be given to a child in doses of 2 or 3 grains with small doses of iodide of potassium and expectorants every 4 or 6 hours. Bromoform is insoluble and difficult to suspend in mixtures; the dose is 3 to 5 minims. Great care is necessary to avoid accidents. Benzyl benzoate has lately been highly recommended—from 5 to 40 drops of a 20 per cent. alcoholic solution being given 3 or 4 times a day according to age and the severity of the disease. Syrup of garlic is also advocated. It is claimed that intramuscular injections of ether in doses of 1 or 2 c.c. given every 2 days reduce the number of paroxysms. The method is painful. Vaccine treatment with the Bordet-Gengou bacillus is still on its trial. The results appear contradictory. Attention should be paid to the condition of the nose and throat, and adenoids removed as soon as possible, since they tend to maintain the cough. During convalescence, quinine and nux vomica are useful tonics, and a change to the seaside is advisable.

Radio-therapy, consisting in one or two exposures of the tracheo-bronchial glands to $\frac{1}{4}$ – $\frac{3}{4}$ pastille dose of X-rays applied to the back through a suitable filter is said to mitigate the severity of the disease and reduce the mortality. The injection of the serum of convalescents, on the same lines as in measles (*q.v.*) has been recommended.

Complications should be treated on general lines. Obstinate vomiting needs careful management as regards feeding, and hydrochloride of cocaine in quarter-grain doses 3 times a day has been recommended. Asphyxial attacks may be treated by pushing forward the lower jaw and applying artificial respiration. Intubation has been practised in some very severe cases.

Although the infectivity of the paroxysmal stage, especially of its latter part, is problematical, patients should be isolated for 5 weeks from the commencement of the whoop, provided the paroxysmal cough and whoop have ceased for a fortnight. The quarantine period for non-immune contacts is 21 days. Disinfection of rooms and clothing is desirable.

CHARLES R. BOX.

ACUTE ANTERIOR POLIOMYELITIS

Definition.—Acute poliomyelitis—an acute, specific, infectious, febrile disease, occurring sporadically and sometimes epidemically—is incident chiefly upon young children, though no age is exempt. It is due to the infection of the respiratory passages with a minute micro-organism, which can be cultivated, and, when injected into monkeys, reproduces the disease, and can again be recovered from the diseased nervous tissue of the infected animals. The clinical aspect of the malady is that of an acute febrile illness of short duration, accompanied or followed by severe nervous symptoms indicative of damage to the grey matter of the spinal cord, brain stem, cerebrum or cerebellum, or any combination of involvement of these structures. The lesion of the spinal cord produces acute atrophic paralysis (*infantile atrophic palsy*), that of the cerebrum produces most commonly hemiplegia (*infantile hemiplegia*), that of the brain

stem produces paralysis of cranial nerves and nuclei (most commonly ophthalmoplegia), and that of the cerebellum, ataxy.

It is probable that the disease frequently occurs without nervous manifestations, as a short febrile illness with complete recovery. Carriers of the disease, who do not themselves suffer, but from whose respiratory passages the organism of the disease can be recovered, are probably common, and these are important agents in the propagation of the disease.

Ætiology.—A most constant feature of the disease is its incidence in young children. During the first year of life, children seem almost immune; but during the second and third years they are most often affected. As age advances after the third year, the incidence rapidly declines, and while cases occurring in early adult life are common enough, the disease becomes very uncommon after middle life. It would appear that the immunity during the first year is acquired from the parent, and that the rarity of the malady in adult life is due either to all the susceptibles having been picked out by the disease in childhood, or to the majority of the community having been protected by the occurrence in early life of an abortive form of the disease without nervous manifestations. The sexes are equally affected, and heredity is not a factor. The disease is much more prevalent during the hotter months of the summer, usually the months of August and September in the northern hemisphere, and the months of March and April in the southern hemisphere. The experimental incubation period in monkeys is from 10 to 20 days. In man it seems to be much briefer, and may certainly be as short as 72 hours from a carrier infection. Since a subject may provedly first carry and then succumb to the infection, the incubation period may be several or many days. There is no satisfactory evidence that the infection can be transmitted by one who is suffering from the disease, since no case admitted into the children's ward of a hospital has ever infected others. The virus seems only transmissible when existing in the purely saprophytic state, namely, upon the mucous membranes of carriers and of those in the incubation stage of the infection.

Though usually sporadic, the disease may become epidemic. The first important epidemic was described by Medin at Stockholm in 1887. Another occurred in Rutland, Massachusetts, in 1894, and in Sweden and Norway in 1899 a very large epidemic investigated by Wickman occurred, and since this time many other epidemics have been reported from all parts of the world. These epidemics have proved that the disease spreads along the paths of human intercourse only, and that it is spread by individuals who are carriers of the micro-organism. No other factors in the spread of the malady are definitely known, although Aycok has collected some evidence of the conveyance of the infection by milk. There seems to be little or no tendency for the disease to occur in institutions, or to spread through the inhabitants of an institution.

Pathology.—In 1909 Landsteiner and Popper and several other investigators succeeded in transmitting acute poliomyelitis to monkeys, by the intrapertoneal injection of an emulsion of the spinal cord from a case of that disease. In the following year Flexner and Lewis, by intracerebral injection of a similar emulsion, were able to transmit the disease through a series of monkeys. In 1913 Flexner and Noguchi succeeded in cultivating the organism of poliomyelitis under anaerobic conditions upon a mixture of ascitic

fluid and fresh kidney. The micro-organism consists of minute globoid bodies, measuring $0.15\ \mu$ to $0.3\ \mu$ in diameter, which are arranged in pairs, chains or masses. They resist the action of glycerin, are capable of passing through the Berkefeld filter, and can be detected in sections of the infected nervous tissue. On inoculation the organism reproduces the experimental disease in monkeys, from which animals it can be recovered in pure culture. Infection either by means of the virus obtained from an infected spinal cord, or by means of the cultivated organism, is most easily produced by direct injection into the brain; but injections into the peritoneal cavity, the anterior chamber of the eye, the subcutaneous tissue, the intrathecal space and the nerve trunks, have all been successful in producing the disease with varying degrees of certainty. Injection into the blood nearly always fails, as the blood seems to have a definite destroying influence upon the organisms. It has been shown that the disease can be communicated to monkeys by applying the virus to the uninjured nasal or intestinal mucous membrane. In living patients during the acute stage, and in those who have died of the disease, the presence of the microbe has been detected in the secretions of the mucous membranes of either the mouth, the nose, the upper air passages or the intestine of so large a proportion of the cases, as to justify the conclusion that the virus is always present upon these mucous surfaces in patients suffering from poliomyelitis during the acute stage, and it is probable that the disease is conveyed from one subject to another by means of the secretion of these mucous membranes. Similarly the presence of the virus has been proved in patients suffering from the abortive form of the disease without nervous symptoms, and in apparently healthy contacts who thus serve as virus carriers.

From the remarkable difficulty in infecting animals with poliomyelitis by means of the blood stream, and from the fact that these can be infected by local injection of the virus into a nerve trunk, and that severance of the nerve trunk upon the proximal side prevents infection, it seems certain that the virus reaches the central nervous system by means of the perineural lymphatics, as is the case also in rabies, tetanus and diphtheria. The virus is never found in the cerebro-spinal fluid. Infection seems to take place directly from one individual to another, by droplet infection from the breath, and the evidence is against the transference of the disease by means of fomites or vermin.

After recovery from poliomyelitis, both natural and experimental, active immunity is developed, and Netter and Levaditi have shown that this immunity is associated with active principles occurring in the blood, which neutralise the virus. Artificial immunity can be produced in monkeys, both by the injection of emulsions of dried spinal cords from cases of the disease, as in rabies, and also by the injection of much-diluted virus. In whatever way infection arrives, the virus is conveyed to the nervous system by means of the perineural lymphatics, and is there fixed in the grey matter, and especially in the grey matter of the spinal cord. It may be found in the fluid of the subarachnoid space very soon after infection; but it rapidly disappears from the cerebro-spinal fluid.

The essential pathological change which occurs in the nervous system is an acute inflammation of the interstitial tissue, especially of the grey matter, with local destruction of the nerve elements according to the severity

of the inflammation, and also a general toxic affection of the nerve cells. In the acute stage the pia mater of the affected region is infiltrated with small round cells some of which escape into the cerebro-spinal fluid, giving rise to the lymphocytosis of that fluid characteristic of poliomyelitis early in the acute stage. All the vessels of the affected region are engorged, and small hemorrhages are not uncommon. The vessels are surrounded by very numerous small round cells which produce a remarkable appearance termed "cuffing" or "muffing" of the vessels. A similar condition of the vessels occurs in rabies, in lethargic encephalitis and in syphilis, but poliomyelitis is distinguished from these by the occurrence of a considerable number of polymorphonuclear cells among the lymphocytes in the perivascular exudation. Sometimes thrombosis occurs in the vessels and this, in addition to the acute inflammation and subsequent necrosis, is the cause of the softening of the affected region which is often present. In the grey matter, in addition to the vascular changes above described, many of the nerve cells are seen to be surrounded by small round cells, and neurophages derived from the glia elements are seen adherent to the nerve cells, and actively destroying them. When the stage of acute inflammation subsides, it leaves a local necrosis which, according to the severity of the initial inflammation, may be so extensive as completely to destroy the affected region, or so slight as to allow of almost complete recovery of function. Subsequently the affected region becomes reduced in size and sclerosed from neuroglial proliferation.

The muscles which are innervated from the affected region waste completely or partially, according to the degree of destruction of the nerve cells. Some of the muscles, such as the biceps, seem always to undergo fibrous degeneration, while others, such as the gastrocnemius, undergo fatty degeneration. The muscle fibres of the muscle spindles do not degenerate, and contain a normal nerve fibre.

Cerebro-spinal fluid.—In the early days of the disease there is usually a pleocytosis, from a moderate to a very large increase of cells: the cells are usually lymphocytes, but sometimes polymorphonuclear cells predominate, both early and late during the pyrexial period; the albumin content is increased; the chlorides are present in normal amount, and the reduction of Fehling's solution is normal. The fluid is clear and under abnormally high pressure. The lymphocytosis is however evanescent, and the cell count usually drops to normal at the end of a fortnight. In a few cases in which the diagnosis was indubitable we have found the cerebro-spinal fluid normal throughout.

Blood.—In the early stages of the disease there is a constant and very marked polymorphonuclear leucocytosis which may reach as high as 30,000, with lymphocytic leucopenia. This leucocytosis soon disappears when the fever abates.

Lymphoid tissues.—All cases of poliomyelitis examined by necropsy show striking hyperplasia of the lymphoid tissues, including the tonsils, the thymus, the lymphoid tissue of the intestine, and the superficial and deep lymphatic glands. The spleen is enlarged and the Malpighian bodies prominent.

Symptoms.—The general febrile symptoms of poliomyelitis are much the same in all the cases and vary only as regards degree of severity. The nervous lesions are, however, local, and, according to their situation and

severity, or their absence, as the case may be, the various types of poliomyelitis have been excellently grouped by Wickman on an anatomical basis as follows: (1) The spinal form; (2) the brain stem form; (3) the cerebellar form; (4) the cerebral form; (5) the meningitic form; (6) the neuritic form; (7) the abortive form. Obviously any combination of the first six forms may occur. Of these varieties only the spinal and the cerebral forms are common.

The onset is abrupt and is usually accompanied by fever, which develops rapidly and lasts but a few days, and rarely longer than 7 days. The fever may be ushered in by a chill in adults, and by convulsions in children, and especially in infants. General malaise, headache and pains in the limbs are complained of by patients who are old enough to describe their symptoms. Very important among the early symptoms and in slight cases are nystagmus, diplopia, and short, jerky, involuntary movements in the outstretched hands. Gastro-intestinal disturbances, such as anorexia, vomiting and diarrhoea are common. When the onset is severe, there may be delirium and stupor with head retraction, pain and rigidity on passive movement of the neck and back, Kernig's sign and incontinence. Usually the skin is flushed and the expression bright, the latter point contrasting with the expression of many forms of meningitis. The muscles are often tender to pressure and the joints painful on movement, and these signs, with the spontaneous pains, may persist for many weeks. In a minority of the cases, the general symptoms are absent or so slight as to escape notice, and the nervous symptoms are the first evidence of illness. This absence of general symptoms and of fever seems to occur only in the spinal form of the disease, and in children.

1. SPINAL FORM.—In young children, the paralysis is often not apparent until the second or third day after the onset. In older children and in adults, the paralysis is usually present within 24 hours of the onset. The paralysis is always of the complete flaccid variety, with loss of the deep reflexes in the region of the paralysis, and subsequent atrophy of the muscles; it develops very rapidly in most of the cases, and seems to have its full limit of distribution at the moment of its appearance. In those cases, however, commencing in the legs, the paralysis spreads slowly upwards and gradually affects trunk and arms successively (ascending or Landry type); or, conversely, it may commence in the arms and spread to trunk and legs afterwards (descending type). In rare cases, after remaining stationary for from 2 days to a fortnight, it may suddenly spread to other regions. This sudden extension, after the lapse of days, has been observed in experimental poliomyelitis in monkeys.

The paralysis is generally much more widely spread at the onset than it is destined to be permanently. Thus all four limbs may be at first completely helpless, and there may be later complete recovery in all but one limb. Here the widely spread temporary paralysis must be due to a toxic and recoverable affection of the nerve cells, whereas the permanent palsy is the result of an actual destruction of the cells by a necrotic lesion. The paralysis may affect any of the muscles of the body, but those of the legs are by far the most commonly involved. The trunk muscles may be affected alone giving rise to marked spinal deformity, usually of a scoliotic or kypho-scoliotic type. The narrowing down of the initial, widely spread paralysis begins to

show itself after the end of the first week, and any muscle which will recover useful power will have done so before the end of the third month. It will occasionally be noticed that the deep reflexes are not lost in the paralysed region in the early days of the disease, and, where this obtains, recovery is always complete. The paralysed muscles undergo atrophy, which is more rapid and complete in those which are to show no subsequent recovery: they show a reaction of degeneration. They are flaccid from the first and in the course of time tend to develop a degree of fibrotic contracture. Any muscles which show response to faradism three weeks after the onset will completely recover. There is usually a considerable degree of vasomotor palsy when a limb is paralysed, and there may be some retardation of growth. Considerable deformities of the body and limbs may arise as the result of the loss of support which results from the paralysis, from the action of unopposed muscles, and from the occurrence of contractures. Such deformities may involve actual dislocation of joints, as in the shoulder-joint, where the deltoid is paralysed and the pectorals escape.

In rare cases, the local lesion of the spinal cord is not confined to the grey matter, but involves also the contiguous white matter of the lateral column, giving rise to signs of lesion of the pyramidal tract and perhaps also of other neighbouring tracts. Obviously, such an extension of the lesion to the white matter neighbouring upon the ventral horn may give rise to loss of pain and temperature sensibility below the level of the lesion upon the whole of the opposite side (Brown Séquard's syndrome).

Paralysis of the cervical sympathetic is not infrequently met with in those cases where the lower cervical and first dorsal segments are involved, with the usual signs of a small pupil and narrow palpebral aperture on the affected side. It is generally a transient phenomenon. When the limbs are affected, paralysis of the blood vessels, most marked at the periphery, is the rule, and there is permanent coldness to touch and pinkness or blueness of the skin, greatly increased by exposure to cold.

In the course of time, the bones of the affected limb may show conspicuous smallness from retardation of growth, if the disease has been incident during the period of growth. They become unduly fragile from a rarefying process, their ridges and bony prominences atrophy and do not further develop, but there is never the same degree of arrest of growth of a limb as is sometimes seen in infantile hemiplegia.

Disturbances of sensibility of an objective kind are rare and are almost always transient, and amount to blunting of pain and temperature sensibility, doubtless from involvement of the spino-thalamic tracts which are contiguous to the ventral horns. Subjective disturbances are common and may consist of severe local pains in the limbs, back or neck. Tenderness of the muscles and pain on moving the joints are sometimes very prominent, and may persist for many weeks. Sphincter paralysis is quite common in the early stages where the lumbo-sacral enlargement is affected, but it is always transient and lasts but a short time.

The reflexes, both superficial and deep, are at first lost in the affected region, and indeed are generally absent throughout the body in the early stages of a severe case, from the general toxic effect upon the nervous system. In the later stages, they return or remain permanently absent, according as the muscles recover or not. Any sign of a returning reflex, either deep

or superficial, in the early days of the illness is a most useful prognostic indication that the muscles concerned with the reflex will entirely recover.

It has been customary to divide the clinical aspect of poliomyelitis into four periods, namely—(1) The period of general febrile symptoms; (2) the period of development of the paralysis; (3) the period of rapid regression of the paralysis; and (4) the period of atrophy and deformities. Such a division, though useful for the purposes of memorising, is largely artificial, the true clinical periods being, before the nervous system is involved and after the especial nervous manifestations have developed.

Course.—The febrile stage with general symptoms may be so little marked as to escape notice, and this is most often seen in young children, but rarely if ever in adults; or it may be exceedingly severe, with convulsions or delirium and stupor. Usually the temperature abates upon the third day, and the entire febrile movement does not last more than a week. The paralysis most often appears on the second or third day in children, and in adults upon the second day. When first apparent, the paralysis is usually complete and does not subsequently spread. In rarer cases, it is slight when first noticed and it rapidly deepens to its full extent. Still less frequently, it begins locally and spreads, constituting an ascending or descending type, and this has been most often met with in epidemics, such as occurred in Scandinavia in 1905. Sensory disturbances and sphincter trouble are often absent, and, when present, usually pass off within a few days of the onset of the paralysis; but in some cases much pain, tenderness of the muscles, and pain on moving the joints may persist for many weeks.

Most commonly within a few days of the onset of the paralysis a very considerable remission occurs, and the paralysis becomes much narrowed down in its limits; thus, with an initial paralysis of all four limbs and trunk, the limbs recovered rapidly, leaving a permanent partial paralysis of the trunk, and in a case where both legs were paralysed, the one recovered power within the first week, leaving the other permanently crippled. Sometimes, however, there is no rapid improvement or narrowing of the region of paralysis whatever. These results are to be explained pathologically in that those regions where the paralysis is due to a toxic effect upon the nerve cells, which is a recoverable lesion, rapidly recover, whereas this does not take place where the nerve cells have been destroyed by necrosis following the inflammatory lesion.

The paralysis remaining after the rapid improvement is final, and admits of such improvement only as may occur from the recovery of a few cells which have escaped destruction upon the confines of the inflammatory lesions, and such recovery is very slow and never reaches more than a slight degree. A certain slow improvement in those paralysed muscles which retain some voluntary power is often observable, and is referable to hypertrophy of function in those elements which remain and to the acquisition of the aptitude which necessity produces. On the other hand, children afflicted with this disease during the period of active growth will often show what seems to be a progressive diminution of power in the weak muscles, and which is, in reality, a relative failure of these muscles under the strain of the increasing weight and length of the body and limbs.

Death is uncommon at any stage in the spinal form of poliomyelitis

except during epidemics, when severe general symptoms are followed by widely spread paralysis, involving all the respiratory muscles, and in these cases it takes place on the first day of appearance of the paralysis. Weakness of the respiratory muscles and especially total intercostal palsy is not infrequently an indirect cause of death, even at long periods after the onset, if bronchitis or broncho-pneumonia occur.

Diagnosis.—During the stage of general pyrexial symptoms and before the nervous manifestations appear, a definite diagnosis can hardly be made; but it may be suggested by the time of year, by the prevalence of an epidemic, and by the combination of a polymorphonuclear leucocytosis in the blood with a lymphocytosis in the cerebro-spinal fluid. When the paralysis first sets in, the diagnosis has to be made from acute rheumatism, in which the painful joints may cause an appearance of severe paralysis. An examination of the reflexes will at once distinguish the two conditions, for both the superficial and the deep reflexes are brisk in rheumatism and lost in poliomyelitis. In the same way, syphilitic pseudo-paralysis (acute syphilitic epiphysitis) may be diagnosed from poliomyelitis. From acute polyn neuritis and Landry's paralysis, both of which maladies may have a pyrexial onset with similar general symptoms, poliomyelitis can generally be distinguished by the sudden onset of the paralysis and by the absence of any spreading tendency, and probably by the lymphocytosis in the cerebro-spinal fluid, and later on, by the permanent atrophic paralysis. In the rare spreading types of poliomyelitis, the latter two points alone serve to make the diagnosis.

From almost all of the local lesions of the spinal cord, membranes and roots, whether these are of rapid onset, as for example hæmatomyelia and acute myelitis, or of slow onset, such as tumour, inflammation and pressure, poliomyelitis is at once distinguished by the absence of the conspicuous sensory loss and sphincter trouble which accompany the former diseases. In the final stage of permanent muscular paralysis and atrophy, deformities and contractures, poliomyelitis presents little difficulty of diagnosis, but it should be borne in mind how frequently deformities of the trunk and especially lateral curvature of the spine have their origin in slight attacks of this malady where the lesions are confined to the dorsal region.

Prognosis.—It is doubtful whether complete recovery occurs in any case of poliomyelitis in which paralysis has once set in. Though in some cases recovery may be nearly complete, yet there seems always to be some region in which permanent muscular atrophy persists, and in cases which otherwise clear up, this is frequently in the spinal muscles, giving rise to a lateral curvature. From this condition of nearly complete recovery to one in which there is not the slightest recovery from the initial paralysis, there is every gradation. The prognosis is not influenced by the severity or otherwise of the general symptoms, for the paralysis may be slight where the general symptoms are severe, and vice versa. Incomplete paralysis or the presence of reflex action, either superficial or deep, in any region at the end of the first week after the paralysis has set in, is a sure indication that useful recovery will occur in that region. Those regions which remain completely paralysed for several weeks after the onset are certain to remain permanently disabled. The prognosis as to the eventual usefulness of disabled limbs, or as to eventual power of walking, depends upon a consideration of the muscles which are permanently paralysed, as to whether they are essential muscles or not, and

whether they can be assisted or supplanted by any mechanical apparatus which is light enough for the weak limbs to carry.

Second attacks of poliomyelitis are exceedingly rare, but two such cases have been recorded by Eshner and by Sanz. The occurrence of progressive muscular atrophy in subjects who have in early life been afflicted with poliomyelitis is not very rare, and it is usual for the progressive atrophy to commence in the region originally affected by the poliomyelitis. Potts has recorded a series of 28 such cases, and several others are to be found among the records of the National Hospital.

Treatment.—In the acute stage, the patient should be kept at rest upon a soft bed and fed upon a diet suitable to the febrile condition. Since the malady is an infectious, specific fever, and since the virus is known to exist upon the nasal, buccal and respiratory mucous membranes, and is presumably spread therefrom, bed and utensil isolation is necessary, with sterilisation of any contamination from the mucous membranes and mild daily disinfection of the mouth and nose. Lumbar puncture should be performed at once and repeated daily for 4 days, and the fluid freely drawn. This operation by itself often relieves the most acute symptoms, and is to be used not only as a method of diagnosis but also as a means of treatment. Salicylates, especially in the form of aspirin, will relieve the pain and fever, and seem to be decidedly beneficial. If pain be very severe there is no contra-indication to the use of morphine. On experimental grounds it is advisable to administer hexamethylamin in large doses, 10 grains (0.6 grm.) 4-hourly, even to young children, the only disadvantage being that this drug occasionally gives rise to hæmaturia. If the respiratory muscles are seriously involved, belladonna or atropine is of great service both in stimulating the respiratory mechanism and in checking accumulation of bronchial secretions. There is conclusive evidence, both experimental and clinical, that the serum of those who have recently recovered from the disease will protect from infection, and if administered early in a developed case will mitigate its severity and lessen or prevent the development of paralysis. Such a serum is to be obtained from the Ministry of Public Health.

Rest and posture.—It is all-important to secure as complete physiological rest as is possible for the weak or paralysed muscles for some time after the onset. Even in the slightest cases, the patient should be kept in bed for at least 3 weeks, during which time attempts at volitional movements should be discouraged. The posture of the paralysed region should be such as to secure the relaxation of the paralysed muscles; for if they are kept stretched by the action of opponent muscles which are not paralysed, recovery is greatly hindered. Appropriate postures can be secured by pillows, sandbags, splints and other devices. After a few weeks have elapsed, massage and passive movements should be regularly employed and re-educational exercises commenced, where there is sufficient power. Electrical treatment in any form is of very doubtful value. Re-education should be assisted by every appropriate mechanical device, but it must be carefully borne in mind that every mechanical apparatus which overweights the weak limb places a millstone around the neck of recovery. The lightest possible shoes should be worn, and if splints are indicated the excellent and almost weightless, moulded, celluloid splints should be employed, to the absolute exclusion of all heavier varieties. In the re-education of the legs for walking,

a walking-machine on wheels is a necessity. Contractures and deformities, which hinder useful action, should be dealt with by passive movements, splinting, tenotomies and other surgical procedures.

2. THE BRAIN-STEM FORM.—In this type, the incidence of the lesions is upon the grey matter of the brain stem from the medulla to the region of the red nucleus. The general symptoms of the onset are as in the spinal form, but there is likely to be in addition head retraction and stiffness of the neck muscles. In place of the paralysis of trunk and limbs there is bulbar, facial, trigeminal or ocular paralysis, according to the situation of the lesions. There may be nystagmus, if any of the cerebellar connections are involved, and tremors, if the red nuclei are affected. An extensive lesion of the medulla itself proves very rapidly fatal. Lesions of the upper brain stem are more commonly survived, and the resulting clinical pictures are, in order of frequency of occurrence, facial paralysis, spastic tremulousness from involvement of the upper part of the brain stem, and lastly ocular paralysis with nystagmus. Any combination of these forms may occur with one another and with the spinal, cerebellar and cerebral forms of the disease.

It is likely that many of the cases of acquired strabismus following convulsion or febrile illness in children are of this nature. Special mention is necessary of the facial paralysis which is usually attributed to a lesion of the facial nucleus. When occurring in conjunction with the spinal or with the cerebral form of the disease its cause is obvious, but when it arises as an isolated event, its origin in poliomyelitis is difficult to determine. It is by no means proved that the commonly occurring facial paralysis in poliomyelitis is due to a pontine lesion at all, and there is very good evidence that it is due to a lesion of the trunk of the facial nerve, for in the cases of facial paralysis which we have seen, associated with well-marked poliomyelitis in other regions and therefore incontrovertible, the facial paralysis has always been of the peripheral and not of the nuclear type; it has always been unilateral and has always completely recovered. Moreover, the well-known association of herpes zoster (which is a peripheral nervous-system lesion) with poliomyelitis, both as a symptom and in the same seasonal prevalence, and its common association with facial paralysis, are evidence that lesions of the peripheral nerve trunks do actually occur in poliomyelitis.

3. THE CEREBELLAR OR ATAXIC FORM.—Here the incidence of the lesion is upon the cerebellum, and the clinical aspect is the acute onset of cerebellar ataxy with vomiting, head retraction, rigidity of the neck and spinal lymphocytosis. Curiously there is often no nystagmus. The nature of such cases of cerebellar ataxy of acute onset in childhood has been proved by the pathological findings, by the coincident appearance of the usual signs of spinal poliomyelitis in some cases, and by the recorded instances of one child of a family being seized with an ordinary type of poliomyelitis and another at the same time with the ataxic form. The cerebellum being an organ in which very great or complete compensation occurs for partial destruction, provided that the damage be not too extensive, it is not surprising to find that many of the cases of cerebellar poliomyelitis make a rapid and complete recovery, while others in which the destruction is presumably much more severe make a slow and gradual improvement.

In the diagnosis of this condition acute symmetrical vestibulitis must be carefully separated. The latter disease resembles the former closely, in that

A pyrexial attack is followed by the acute onset of severe cerebellar ataxy, but in acute vestibulitis the patient becomes rapidly and permanently stone deaf, and all the other symptoms soon disappear. Many of the cases of acute vestibulitis have been diagnosed as cerebellar poliomyelitis with brain stem involvement affecting the auditory paths, but a moment's consideration will make it clear that no gross lesion of the nervous system can produce permanent and complete bilateral deafness as the sole result.

4. THE CEREBRAL FORM.—The characteristic clinical features of this type are usually very distinct. After a period of pyrexia and general symptoms of variable severity and length, the patient is seized with convulsions which are remarkable for their severity and duration, it being no uncommon thing for the convulsions to recur frequently for the space of a dozen or more hours. When the convulsions cease, the patient remains in a subconscious state for many hours, often for several days, and at the end of this time he gradually rouses to reveal the physical signs—motor, sensory, psychic, or some combination of these—of the cerebral lesion. The lesion may be unilateral, when the commonest result is a hemiplegia, or may be bilateral, giving rise to a double hemiplegia, and in some cases the central regions of the brain escape, while other regions are seriously involved, giving rise to marked mental defect which may be so great as to amount to complete restless idiocy. Local incidence of the lesions upon the various regions of the brain may cause a very varied clinical aspect. In one case under the care of one of us, a hemiplegia was associated with hemianopia of the opposite side. Not very infrequently the basal ganglia are the seat of destructive lesions with the appearance of spontaneous, involuntary movements, which may be of an athetoid, choreic, myoclonic or tremulous type. Of these, athetosis is by far the most commonly met with.

Notwithstanding what has been said to the contrary by many writers, it seems certain that cerebral poliomyelitis is by far the most common cause of infantile hemiplegia. It is my opinion that infantile hemiplegia due to any cause other than poliomyelitis is very rare. It is the rule for one-third of all cases of cerebral poliomyelitis to develop recurring epilepsy at a later age.

5. THE MENINGITIC FORM.—One of the most interesting types of poliomyelitis, which frequently gives considerable difficulty in diagnosis, is the meningitic form of the disease. The onset is sudden and is occasionally attended by convulsion and coma. The temperature is raised and may remain high for days, and the usual symptoms of meningitis are present. Headache and vomiting occur. The neck is stiff and the head may be retracted; there may be opisthotonos and rigidity of the legs, and Kernig's sign is commonly present. Lumbar puncture reveals a cerebro-spinal fluid, clear and under pressure, which on cytological examination may at first show no abnormality, but as the days elapse will contain an increasing number of lymphocytes, an increased amount of albumin and diminished sugar reaction.

There are certain clinical points which will sometimes serve to distinguish this type of the disease from other conditions of lymphocytic meningitis. In many of the recorded cases and in many which we have seen, careful examination has revealed a local, flaccid palsy of some part of a limb, and, if such a palsy is present, it should go far to settle the diagnosis. Again, a flushed face and bright expression are characteristic of poliomyelitis and contrast strongly with the pale, dull faces of tuberculous meningitis. Lastly, it is the rule

for the meningitic form of poliomyelitis to recover and leave no intracranial sequelæ, and this will distinguish it from the invariably fatal tuberculous meningitis.

The other common forms of lymphocytic meningitis are those due to tubercle, sinus thrombosis, mumps, measles, lethargic encephalitis and syphilis. In any questionable case, the discovery of the tubercle bacillus in the spinal fluid will settle the diagnosis, and a mixed polymorphonuclear and lymphocyte count with high lymphocytes is characteristic of tubercle. The history in the case of mumps and measles, and the Wassermann reaction in the case of syphilis, are important guides in the diagnosis. The treatment is that of poliomyelitis and meningitis in general.

6. THE NEURITIC FORM.—It has been shown in the foregoing pages that the poison of poliomyelitis does cause a widely spread temporary abolition of function of the lower motor neurons, quite apart from the destruction of these same neurons by the local inflammatory lesions, and that the rapid improvement which occurs early, is due to a passing off of this toxic effect. The question then arises as to whether this same virus can cause the toxic effect, without giving rise to any local inflammatory lesions. In other words: can the virus of poliomyelitis produce a polyneuritis? Wickman and other investigators of epidemics of poliomyelitis affirm that it can and does do so, and have recorded many examples. While the truth of their contention is probable, yet the only infallible proof that such cases, even though occurring in an epidemic of poliomyelitis, were really examples of that disease, the recovery of the virus from the patients was not established; the reason being that all these patients recovered.

7. THE ABORTIVE FORM.—This type of poliomyelitis may be described as corresponding with the initial stage of febrile and general symptoms before the appearance of the paralysis. The general bodily infection with the virus occurs, but it does not reach the nervous system, or affects it so little as to cause no characteristic symptoms. The attack as a rule is acute, with fever, headache and malaise, and in some cases slight nervous symptoms such as rigidity of the neck, pain in the neck and back and limbs. Paræsthesias occur. These symptoms are not followed by paralysis and recovery occurs within a few days. Except when poliomyelitis becomes epidemic, it is hardly possible to detect the abortive forms of the disease. Nevertheless, since an epidemic of this disease among a population seems to immunise the whole population and remove all susceptibles, so that in a subsequent epidemic only those born since the previous epidemic are affected, it seems clear that affection with the slight abortive form of the disease was the cause of the immunity.

Doubtless in a country such as England, where poliomyelitis never has been epidemic, the abortive form occurs frequently enough among the commonly occurring short febrile illnesses of children, which at present do not admit of definite diagnosis.

LETHARGIC ENCEPHALITIS

Early in the year 1917 an epidemic disease was recognised in Vienna, characterised by signs of general intoxication, bilateral ophthalmoplegia and marked drowsiness, to which Economo gave the name "Encephalitis

lethargica." In the following year cases appeared in France and in England in increasing number, and Netter, who investigated many of the French cases, drew attention to an epidemic of an apparently similar condition which appeared in Northern Italy in 1890, to which the name "Nona" had been given, cases of which seemed to have occurred in various parts of Europe during the years 1891-92. Mauthner made a pathological research upon "nona" in 1890, and was of opinion that the disease was of the nature of an acute hæmorrhagic poliomyelitis superior. It is suggested that the epidemic disease occurring in the fifteenth century and known as the "Sleeping Sickness of Tübingen," and that of the middle of the nineteenth century occurring in Northern Italy known as "Dubini's Electrical Chorea," were examples of lethargic encephalitis. It seems certain from the investigation of end cases still living that a few cases of lethargic encephalitis were occurring in England as early as 1914. The disease has subsequently become scattered world-wide.

Ætiology.—The disease seems to occur both sporadically and epidemically with no centre of spread. There is no evidence as yet to show that the disease is infective in the sense that it may be conveyed from one human being to another, the cases being for the most part widely and sparsely scattered through the country. It is more prevalent in the cold season of the year. No age appears to be exempt from the disease, and cases have occurred in the seventh decade of life, but the malady is rare in young children and seems to be most common in the first half of adult life.

Pathology.—The malady has no relation with botulism, as was at first thought by some observers, for it has no known association with food, and the *Bacillus botulinus* has never been present. Nor is it an aberrant type of poliomyelitis as was at first argued, for its age incidence, seasonal prevalence, morbid anatomy and symptomatology are quite different from those of the Heine-Medin disease. Neither does it seem to have any relation to influenza, although the height of its epidemic incidence has twice coincided with a severe epidemic of influenza. Straus, Cleland and others have claimed successful transference of the disease to monkeys by the intra-cerebral inoculation of monkeys with an emulsion of nervous tissue from a human case. Loewe and Strauss have recently claimed to have grown in pure culture on Noguchi's medium an organism (globoid) resembling that discovered by Flexner in poliomyelitis, and that subcultures carried through several generations have reproduced the disease and its histological picture in animals. They have obtained the organism from the nervous tissue, cerebro-spinal fluid, blood and nasal mucous membrane in human cases. These results appear to have been subsequently fully confirmed by Thalhimer.

Cerebro-spinal fluid.—In at least one-third of the cases the cell count is normal. In the rest, there is a leucocytosis consisting entirely of lymphocytes which may reach to over 100 per c.mm. The presence or absence of lymphocytes, and their number when present, seems to have no bearing upon the severity or prognosis of the case, nor upon the post-mortem picture, for we have several times seen persistent absence of lymphocytes when autopsy showed intense meningeal congestion.

The globulin content is hardly increased, and the reducing bodies do not disappear. Lange's colloidal gold reaction shows definite abnormalities, and the positive curves are said to be of the lætic and parætic types. Blood may occur in quantity from surface hæmorrhages.

Naked-eye examination of the brain shows a characteristic change from the colour of a normal brain, which varies from a faint rosy flush to a deep salmon-pink. It has been termed the "rose-coloured" brain. When hardened in formalin, the colour becomes a dusky purple-grey. On section, the grey matter throughout the cortex, basal ganglia and brain stem presents the same curious colour, and thus the usual distinction between grey and white matter becomes very much more conspicuous. It must be remembered, however, that in some cases, and even in severe and rapidly fatal cases, this characteristic colour may be little marked. The brain seems to be generally more full of blood than normal. Subdural hæmorrhages may be present, and these may be of considerable size. Deeply seated hæmorrhages may also occur, especially in the region of the basal ganglia and brain stem, and when large these may be confused with the hæmorrhages of apoplexy.

The microscopic appearance is that of vascular congestion with conspicuous lymphocyte "cuffing" round the small vessels. Microscopic hæmorrhages are rare. The nerve cells show the different stages of toxic degeneration with neuronophagia, they become swollen, chromatolysis occurs and the nucleus becomes eccentric. The degeneration of the cells is often very local; one group of cells may be severely affected and a neighbouring group intact, or some cells of one group may be affected and others intact. The distribution of the lesions varies greatly; and while there is no part of the nervous system which may not be affected, there is an especial selective incidence upon the grey matter of the basal ganglia and brain stem, and this corresponds with the more commonly occurring clinical symptoms of the disease, which indicate lesions in these regions. Of importance in connection with the paralyses of single peripheral nerve trunks in the clinical picture of this disease, are the perivascular and diffuse infiltrations with round cells, sometimes accompanied by small hæmorrhages, which are found around the cranial and spinal nerve roots. In cases which run a chronic course with remissions, scattered inflammatory lesions may be found at every stage of their development, from the earliest changes to the healed lesion.

Symptoms.—Considering that the pathology of the disease is one of multiple and widely disseminated patches of infection of simultaneous origin, it is to be expected that the clinical manifestations of the disease will show wide variations as to their nature, acuity and duration.

The onset is in many cases insidious, and it may take a few days to 2 weeks before the symptoms become sufficiently pronounced to allow of correct diagnosis. In other cases, however, the onset of general symptoms is sufficiently rapid to have given rise to a diagnosis of influenza. The nervous symptoms, too, follow upon the general symptoms insidiously, as a rule, but these may be in some cases startlingly rapid or even sudden in their appearance. Though lethargy, nuclear ophthalmoplegia, paralysis agitans-like rigidity and aspect, spontaneous involuntary movements and obstinate constipation dominate the clinical picture in 70 per cent. of the cases, yet any or all of these signs may be absent, and other signs be prominent, the nervous symptomatology depending upon the position of the lesions. The clinical aspect may be conveniently considered under two divisions of manifestations, the general and the nervous.

GENERAL SIGNS.—The general signs are those of general toxic infection, and consist of fever sometimes accompanied by rigor. Sometimes the pyrexia

is severe, and this usually marks a rapid and fatal case, but often the fever is so slight as to escape notice. Headache, bodily pains and malaise are common. Gastro-intestinal symptoms are frequently met with in the form of a thickly coated white tongue, vomiting and hiccough, and obstinate constipation is highly characteristic of the malady. Cutaneous eruptions of an erythematous nature may be seen. The severity of the general symptoms of intoxication is extremely variable, but there is no parallelism between this and the degree of involvement of the nervous system, though severity of initial general symptoms renders the immediate prognosis as regards life grave. The pyrexia does not usually last longer than a week.

THE NERVOUS SIGNS.—*Mental symptoms.*—An increasing lethargy, which often becomes very deep, is present in many of the cases. In this condition the patient will lie for days without stirring a muscle, taking no heed of his surroundings and passing the dejecta under him unheeding. Yet when roused by command and vigorous bodily stirring, he will wake up and hold a very intelligent conversation, lapsing back at once when he is left alone, even though his mouth be half full of unswallowed food. In this condition, *flexibilitas cerea* may often be demonstrated in the limbs. The lethargy may last for 3 weeks or longer even in patients who completely recover. It passes away gradually. Unrousable coma is invariably a sign of impending dissolution. Subsequent memory of events during the early days of the lethargy may be remarkably retained. Insomnia may be a troublesome early symptom, and even when the patients are markedly lethargic they will complain that they cannot sleep. Lethargy, however, may be completely absent and the early mental state be that of vivacious excitement and talkativeness. Irritability and restlessness may be present. In some cases the first nervous sign may be delirium or mental aberration, which may rapidly develop into acute and violent mania; such cases are rapidly fatal. In cases which recover after severe symptoms, considerable mental reduction and self-obvious mental change may persist, but I have not seen any case in which insanity resulted. Indeed, it has been said that no sufferer from this disease ever regains his original mentality, and it is a common experience to find personality very seriously changed in the way of mental reduction. Complete incapacity for any sustained work, entire change of character, anti-social tendencies, moral perversion and depressed neurasthenic states are not uncommon sequels of the disease. (See also page 1710.)

Convulsions are rare, but they may undoubtedly occur as in other forms of encephalitis. Indeed, the initial clinical picture may be dominated by convulsion, and closely resemble "status epilepticus" from other causes.

Ophthalmoplegia and other paralyses in the region of the cranial nerves are most often nuclear in type, but peripheral paralysis of any cranial nerve may be met with, most commonly unilateral paralysis of the facial nerve. The pupils may show every abnormality which a lesion of the nervous system can produce. Inequality, unroundness, eccentricity and Argyll Robertson pupil and ciliary paralysis may occur. The Argyll Robertson pupil may be unilateral. The external ophthalmoplegia, being nuclear in origin, involves both eyes in terms of their conjugate movements, and the upward and downward movements are as a rule more severely impaired than are the lateral movements. Bilateral ptosis is very usual, and is a most important and valuable early indication of the disease. The common error is to consider it part

of the sleepy state. The nuclear ophthalmoplegia is often irregular, giving rise to strabismus and diplopia. Either in addition to the above or existing alone, there may be peripheral paralysis of any of the oculo-motor nerve trunks. The degree of the ophthalmoplegia varies in different cases from slight diplopia with hardly noticeable strabismus to complete paralysis of both eyes. It may be rapidly transient or permanently severe. In severe cases which survive, there is always some improvement in the degree of paralysis in the course of time.

Vision.—The diplopia and loss of accommodation cause much defect of vision, but many of the patients complain of a loss of vision in each eye, which is too great for any such explanation, the cause of which is not yet explicable. Papilloedema has been reported in a few cases, in one of which at least meningeal hæmorrhage had occurred. It is transient and never reaches a high degree.

Oculogyric Crises.—This term is applied to recurring attacks of tonic conjugate deviation of the eyes, most commonly upwards, sometimes upwards and to one side, less commonly downwards, or downwards and to one side. We have not seen any case with pure lateral deviation. The spasm is met with in the chronic stage of the malady, and there is always some degree of Parkinsonism. The attacks may last from a few seconds to 4 hours or more, and may occur frequently or at intervals of several days, and as the eyes are commonly fixed in an upward direction, they are peculiarly incapacitating. They have not been reported in any other disease than lethargic encephalitis, and may constitute, with some slight facial Parkinsonism, the sole sequela of this malady. We have not found any treatment which influences the frequency or severity of the attacks.

Bilateral nuclear facial paralysis and bulbar paralysis are not uncommon. Paralysis of any individual cranial nerve may occur, and also of any individual spinal root. Such paralysees always completely recover in the course of time.

Symptoms indicative of lesion of the basal ganglia are among the most common features of the disease, and they are often the most persistent. These consist of weakness of movement, rigidity with slowness of movement, and spontaneous involuntary movements. The weakness, rigidity and slowness of movement give rise to a peculiar immobility of facial and bodily expression and movement. The face is mask-like, the neck stiff and the head moved little and slowly, the trunk bent forward and stiff, the arms held away from the trunk, the whole appearance of the patient closely resembling that of paralysis agitans. Rapid fluttering of the eyelids when gently closed is characteristic of this condition. The spontaneous involuntary movements may be of a rhythmic tremulous nature, as in paralysis agitans, or there may be slow rhythmic choreiform, athetoid, myoclonic, irregular or highly complicated movements: these may be met with at any stage of the malady, but most commonly appear some little time after the acute stage has passed away. Fibrillation and fascicular twitching of the muscles is very common in the acute stage. In cases where bulbar symptoms, either of a spastic or flaccid kind, are present, hypersalivation of the nature of a true sialorrhœa is often a most troublesome, though transient, symptom.

In addition to the above common symptoms and signs, other indications of involvement of the cerebral hemispheres may occur. Bilateral spasticity with signs of involvement of the pyramidal systems, increased jerks, lost

abdominal reflexes and extensor plantar responses are common. Hemiplegia, aphasia and hemianopia may occur, presumably as the result of local sub-cortical hæmorrhages. Meningeal symptoms may be very marked in the early stages, such as suboccipital headache, painful stiffness of the neck, head retraction, vomiting and Kernig's sign. Indeed, we have seen rapidly fatal cases in which the clinical picture throughout was hardly distinguishable from that of acute meningitis, but none of these cases showed any leucocytosis in the cerebro-spinal fluid. A major incidence of the lesions upon the cerebellum gives rise to the picture of acute cerebellar ataxy following a lethargic onset, and the end result may be a condition closely resembling a usual type of disseminate sclerosis. Such cases make a good recovery in the course of time.

Peripheral pains are sometimes very severe and are usually quite local. They may be the first signs of the illness, and several of my patients had been treated for trigeminal neuralgia, brachial neuritis or sciatica before any other sign of the malady appeared. These pains may persist for months after recovery. They are obviously due to the lesion around the nerve roots which has been already referred to.

Spinal symptoms.—Since the lesions have been found in the spinal cord, it is only to be expected that focal spinal lesions should be met with in rare cases. These are usually acute atrophic paralyses similar to those of poliomyelitis. Those that we have seen have completely recovered. It has been argued, however, that this atrophic palsy is due to a lesion of the spinal roots. More severe lesions may apparently give rise to a condition resembling acute transverse myelitis.

Sphincters.—The incontinence which is almost constantly present, even when the lethargy is far from deep, is the result of the lethargy. Transient conscious dysuria is however not infrequent in the early stages of the disease. The deep reflexes may be lost in severe cases during the acute stages, and they are usually absent in pre-mortal conditions. Otherwise they tend to be exaggerated, especially if involvement of the pyramidal system be present. The condition of the abdominal and plantar reflexes depends upon the presence or absence of lesions affecting the pyramidal tracts. In the former case, the abdominal reflexes will be absent and the plantar reflexes of the extensor type.

Attention must be drawn to a group of cases in which the initial manifestations of the disease are so slight as not even to interfere with the daily work or to call for medical attention, and yet in the course of months, or it may be even years, the most serious and completely incapacitating paralysis appears. A patient of ours noticed that he saw double, and did not feel very well for a few weeks. He recovered, but 2 years later, had to give up work, by reason of a slowly oncoming Parkinsonism, which became extreme. A similar result in the slow and late development of grievous symptoms may follow any attack of lethargic encephalitis and make the prognosis in this malady very difficult.

Sequelæ.—The disabilities which this malady may leave in its wake seem endless and ever increasing as clinical experience widens. The mental, paralytic and Parkinsonian end-results have already been referred to, but special mention must be made of involuntary spontaneous movements, recurring rhythmic movements, spasms and altered respiratory rhythm.

Ceaseless rhythmic pulsatile movements may occur in any muscle, movements like those of convulsive tic may incapacitate the patients. Hideous recurring spasms may appear, sometimes local, sometimes general. Torticollis may occur. An unduly rapid respiratory rhythm may be established. (See also p. 1563.)

Course.—The course of the disease is extremely variable. It may be a slight transient illness lasting but a few days, and leaving no sequelæ after a few weeks; or a most malignant disease, fatal in a few days. Some patients, apparently recovering at the end of a fortnight, succumb to meningeal or deeply seated hæmorrhage. In others, symptoms indicative of fresh lesions may occur repeatedly, weeks and even months after the onset.

Diagnosis.—In typical cases the diagnosis presents no difficulty, the rousable lethargy, incontinence, ophthalmoplegia and negative, lymphocytic, or blood-containing cerebro-spinal fluid being so characteristic as to preclude possibility of error. The less usual forms of the malady, and especially those with very gradual onset and slight symptoms, often present great difficulty and require much care and full knowledge of the possible symptomatology of the disease for their recognition. There is no specific laboratory test for the malady, and the diagnosis must be based upon clinical grounds. Where meningeal symptoms are prominent, distinction has to be made from other forms of meningitis and from poliomyelitis. Here, the cerebro-spinal fluid is of the highest importance, as no polymorphonuclear leucocytes occur in lethargic encephalitis. In cases commencing with peripheral pains, excitement, maniacal symptoms or convulsions, careful look out should be kept for the advent of ptosis, ophthalmoplegia, or lethargy, the appearance of which, following such symptoms, should at once suggest the diagnosis. It must be borne in mind that the clinical picture of the disease may be dominated by a hemiplegic condition, and that an apoplexy may occur during the acute stage of the disease. Slight cases of the disease are frequently unrecognised, or are indeed unrecognisable in the early stages, but here the diagnosis can often be made with certainty from the end results; the peculiar ophthalmoplegia, the spontaneous involuntary movements, and the paralysis agitata-like syndrome being almost pathognomonic of the malady.

Prognosis.—A rapid onset and quick development of severe symptoms, marked pyrexia, delirium and maniacal excitement are bad prognostic signs and indicate a rapidly fatal issue. After the third week of the disease, the probabilities are all in favour of survival. The prognosis however as to how much permanent damage to the nervous system will eventually remain is hardly possible, since slow improvement may go on for months and even years. The spontaneous movements, even when very marked, may clear up in from 3 months to a year. The weakness, rigidity and tremors, which form the paralysis agitata-like picture in many of the cases, persist indefinitely.

Treatment.—Nothing being known of the infectivity and mode of spread of the disease, isolation and disinfection are not usually employed. Each case must in England be immediately notified to the public health authorities. No treatment is known which has any specific influence upon the disease. Intravenous injection of colloidal iodine solution (150 c.c. for a dose), repeated on the second and fourth days, has been advocated, and is certainly without harmful effects. Intravenous salicylate of soda, in 15-grain doses in normal

saline daily, certainly seems to clear up the symptoms in some cases and may do permanent good. It remains therefore to use those measures which will help to keep the patient alive and those which relieve symptoms. Relief of the constipation is most important and is often followed by striking improvement in the symptoms. The presence of blood in the cerebro-spinal fluid, or symptoms indicative of intracranial hæmorrhage, should call for the exhibition of opium, turpentine and calcium salts, and lumbar puncture should be repeatedly performed. After the acute stage, treatment is concerned with combating the physical and mental listlessness and depression, removing the rigidity with massage, passive movements and exercise, and withal brightening the days of a convalescence which is often long, tedious and hard to bear.

JAMES COLLIER.
W. J. ADIE.

CEREBRO-SPINAL FEVER

Synonyms.—The name here chosen seems least open to objection. "Cerebro-spinal meningitis" is the best alternative, but cerebro-spinal meningitis may be caused by other micro-organisms than the meningococcus, and meningitis may not be present at all, or may not constitute the chief lesion, in some cases of meningococcus infection. "Epidemic cerebro-spinal meningitis" is much less desirable, because it suggests that there is an essential difference between the epidemic and the sporadic cases of meningococcus infection, which difference does not in fact exist. "Meningococcus infection" brings the various pathogenic possibilities of the micro-organism into line with those of the pneumococcus, with which it has close analogies, but the term does not connote a disease.

Definition.—A specific disease, due to infection of the body by the meningococcus, occurring both in epidemic and in sporadic form, and most often manifesting itself as an acute meningitis tending to involve the whole cerebro-spinal axis.

Epidemics of cerebro-spinal fever are marked by several features peculiar to the disease, offering a striking contrast with other epidemic diseases. For a long time these features were very difficult of explanation, until the existence of "carriers" became recognised, and supplied the solution to much of the epidemiological problem. Amongst these curious features may be mentioned the erratic nature of the outbreaks, the inability to trace the connection between one epidemic and another, the relative or even total escape of certain localities close to others in which the disease was rife, and the small proportion of persons affected in any one district.

On clinical, bacteriological and epidemiological grounds there is no distinction to be drawn between sporadic and epidemic cases of cerebro-spinal fever. But it is not entirely by means of the sporadic cases that the infecting agent persists, but by "carriers" also. There is little doubt, however, that from the sporadic cases, as from a smouldering infection, new epidemics light up. The present conception of the disease, from an epidemiological point of view, is that of a very widespread infection, with a total morbidity that is very low, but with foci of more intense virulence here and there. These foci of more intense virulence appear and disappear, being

preceded and followed by a somewhat higher level of permanent incidence in the districts concerned.

Ætiology.—The geographical distribution of the disease is very wide—world-wide, in fact. A certain affinity is shown for the north temperate zone.

Epidemic cerebro-spinal meningitis is a disease of winter and spring. This seasonal incidence is borne out by all observers, and is a very important feature of the disease. It compares markedly with the seasonal incidence of poliomyelitis epidemics, which are at their height in the summer months.

Epidemics of cerebro-spinal fever are prone to coincide in time with recrudescences of influenza, pneumonia, measles and scarlet fever. It is doubtful if this is more than a fortuitous observation. The naso-pharynx is liable to catarrhal inflammation in all these diseases, and pneumonia and influenza have the same seasonal incidence as cerebro-spinal fever.

The question whether cerebro-spinal fever is contagious or not has been a matter of much dispute. The facts would appear to indicate that the disease is contagious, but that the degree to which it is so is very slight. The proofs of the contagiousness of the disease are, briefly, these:—(1) the occasional transmission of the disease to doctors and nurses; (2) the occurrence of a succession of cases in one family and in the same house; (3) the importation of the disease into a new country or locality; (4) the mode of spread in any locality; (5) the immunity enjoyed by collections of persons living under the same conditions as those affected by the disease, but unable for some reason to come into contact with them (Netter and Debré). Although direct contagion is uncommon, plenty of authentic instances of its occurrence have been reported.

THE MENINGOCOCCUS.—The meningococcus (*Diplococcus meningitidis intracellularis* of Weichselbaum) is rather smaller than the *M. catarrhalis* and larger than the gonococcus—the other two pathogenic diplococci which are Gram-negative in staining reaction. It is an obligatory anaerobe, requiring the addition of some animal protein to ordinary culture media to ensure growth. After cultivation for three or four generations it will grow on ordinary agar, but sub-cultures die rather suddenly. Optimum growth takes place at 36° to 37° C., and growth ceases at 42° C. and at 25° C. Vitality is low, especially to drying; sunlight kills in less than 12 hours.

Serum Reactions.—1. *Agglutination.*—Great difficulties are presented by the nature of the micro-organisms (having inherent tendencies to clumping). But the existence of different strains, differing in serum reactions, is rendered certain by the use of "absorption" methods.

2. *Fixation of complement.*—This method is perhaps less reliable for diagnostic purposes than (1).

Types of the Meningococcus.—By employing the agglutination test, controlled by the absorption test, M. H. Gordon has differentiated four separate types of meningococci occurring in the cerebro-spinal fluid of actual cases.

IMMUNE SERA.—These were proved by Jochmann and by Flexner to possess potent immune substances when prepared from the horse by the usual technique. Standardisation is still, as in the case of nearly all bactericidal sera, almost impracticable. The great advance of the past few years has been the preparation of type-sera, following Gordon's researches. By the use of these the results of serum treatment, hitherto somewhat disappointing in this country, promise to be much more successful.

The primary habitat of the meningococcus, both in actual cases of the disease and in "carriers," is the upper part of the naso-pharynx and the posterior nares. West has devised a special sheathed swab for obtaining mucus from this region.

Symptoms and Course.—Cerebro-spinal fever is protean in its features and especially in its modes of onset. Out of the large number of different manifestations that occur, certain cases repeat themselves with sufficient constancy to constitute clinical "types," capable of description and of recognition.

1. **THE ORDINARY OR ACUTE TYPE.**—The incubation period is difficult to estimate with accuracy; there are reasons for considering it to be 4 or 5 days. The illness begins with the usual symptoms of an acute specific fever, and for the first day or two, or for longer than this if the possibility of the disease under consideration is not borne in mind so as to lead to a special examination, there may be nothing to distinguish the illness from one or other of several acute febrile infections.

The onset is usually sudden, with fever, headache, general malaise and vomiting. The temperature usually rises rapidly and attains a fairly high degree on the first day (102° to 104°).

The headache is usually very intense, is often referred to the occiput, and shows little or no response to the customary palliative drugs given to relieve it.

There is frequently a rigor in the adult, or a convulsion in the infant or child. Vomiting is more often met with in children than in infants, and is quite common in young adults.

In addition to the three cardinal symptoms at the onset—headache, fever, and vomiting—the following are quite common, but are not nearly so constant: delirium, pains in the neck and limbs, and some degree of catarrh either of the nose, naso-pharynx, conjunctiva, or ear. In some cases there is considerable bronchial catarrh and in others definite enteritis. In addition to the pains referred to the limbs there may be pain and swelling of the joints.

After some 2 to 4 days of these initial symptoms evidence of meningeal irritation begins to show itself in more or fewer of the following developments. The vomiting is repeated, despite the fact that the invasion symptoms are past. The pulse is irregular in rhythm, and in older children and in adults it is often relatively infrequent when compared with the height of the temperature. The respirations are irregular. The vasomotor system is unstable, leading to periodic flushing of the face and to the presence of *tâches cérébrales*. The patient lies on his side with legs drawn up and prefers the shelter of the bed-clothes. The pupils are dilated and the light reflex is sluggish. There is photophobia, with intolerance of noise and of all kinds of interference. Examination of the neck reveals a stiffness of the muscles, which cannot be overcome without pain. The hamstrings are found to be taut, so that the knees cannot readily be extended if the hips are flexed (Kernig's sign). The abdomen is retracted and the superficial reflexes are abolished. The mental state is one of restlessness and mild delirium with troublesome insomnia. The headache may become quite intolerable and may require morphine for its reduction. In a considerable number of cases a rash appears during the first week—either a number of large rose spots about the trunk and limbs, or a macular eruption like that of measles, or a

few small petechiæ scattered over the trunk, neck and extremities. Herpes is common, and is generally situated at the usual places—the angle of the mouth, the chin and the nose. There is a leucocytosis of considerable degree (20,000 to 40,000).

Towards the end of the first week the mental state changes to a condition which may perhaps best be described as one of resistant stupor: the patient can be roused by an effort at examination, or by a change of position; but either proceeding is resented, and he quickly resumes his huddled posture. The headache is less constantly severe, but shows sudden and marked exacerbations, often nocturnal, with complete insomnia. The neck rigidity increases, and the head is retracted. The back also becomes stiff. Flesh is lost rapidly. Polyuria is common, with polydipsia. The temperature generally remains fairly high, and, although this is by no means invariable, the fever approximates to the continued type.

Assuming that the course of the disease is not interrupted by lumbar puncture or by specific therapy, the condition of the patient remains much the same during the second, and perhaps during the third, week of the illness. But the wasting continues. The temperature often becomes intermittent in type. One of the three modes of termination will be followed.

(a) *Recovery*.—This is gradual when it occurs, and is often interrupted by sudden recrudescences, throwing the patient back into a state which leads to renewed anxiety. The temperature chart is often interrupted in its deferescence by sudden rises, with or without a corresponding recrudescence of the meningitic symptoms. Ultimately the fever completely subsides, the patient ceases losing flesh, the headache and stupor pass off, and the rigidities slowly disappear. The pulse-rate remains high for some time in a good number of cases, and some authors regard this as a sign that the patient is not yet free from the possibility of relapse, and therefore as an indication for caution in treatment. The actual stage of convalescence, once it is established, is rarely interrupted. If the temperature and pulse-rate have remained normal for fourteen days, the risk of relapse may be considered to be passed. It may be some weeks, however, before the patient is free from stiffness.

(b) *Death*.—The ordinary type of the disease is not often fatal during the first 2 weeks. When it is, the stupor passes into true coma, the pulse and respiration rise in frequency, and the temperature often shows a sudden ante-mortem rise.

(c) *Becoming chronic*.—More often, if the ordinary type terminates fatally, it is by passing into a subacute or chronic stage. If the "crises" already referred to continue, or if, despite the fall of temperature, there is no corresponding improvement in the general condition, a state of progressive emaciation supervenes, with a tendency to chronic hydrocephalus. The wasting is sometimes extreme, so that bedsores are unavoidable. The rigidity becomes marked, and approaches, even in adults, that degree termed *cervical opisthotonos* in infants. Feeding becomes difficult, and this adds to the wasting due to trophic disturbances. The sphincters usually relax, leading to incontinence. Papillœdema develops. The patient may continue in this unsatisfactory state for several weeks, or even months, and yet may eventually recover, and without any residual defects. More often, however, he gradually succumbs to the disease, or, if he eventually survives

its ravages, it is to be left with mental defect, deafness, blindness, hemiplegia, or diplegia.

Opinions differ as to the frequency of true relapses in cerebro-spinal fever. This is probably due to the fact that what some authorities term relapses others consider to be merely recrudescences. It is certain that the latter are very common; indeed, they are a characteristic feature of the disease.

2. **THE SUPRACUTE TYPE.**—This form of the disease is common at the height of an epidemic. The invasion symptoms are abrupt, and the patient is from the first very ill. Delirium is marked, with most tiresome insomnia, and the headache may drive the patient to a state of acute mania. The temperature is usually very high (104° to 106°), and intermits. Skin eruptions are more constantly present than in the ordinary type; but are by no means necessarily petechial in character. Discharges are apt to occur from the nose and conjunctival sac. The tongue is dry and tremulous. The meningococcus can generally be grown from the blood by culture, and may even be demonstrated in cover-slip preparations made from the blood direct. The leucocytosis is high (30,000 to 40,000). After 3 or 4 days the active mental state changes to stupor; if the cerebral pressure is not now relieved by lumbar puncture this stupor passes into coma. Even if the pressure is relieved by this procedure there is a great tendency for the patient to slip back into a comatose state; then, with pulse, respirations and temperature all rising, with insensitive pupils and absence of corneal reflex, the surface of the body becomes livid, the lungs congested, and death occurs.

3. **THE FULMINATING OR MALIGNANT TYPE.**—This form is prone to occur during the evolution of an epidemic. But it is by no means rare as a sporadic manifestation of the disease. It is more often seen in older children, adolescents, and adults than in infants and younger children. The abrupt appearance of fever, headache and active delirium, rapidly passing into coma, and the whole course of the disease may not exceed 12 hours.

In all fulminating cases of cerebro-spinal fever there is a rapid development of septicæmia. In some of them the septicæmia covers the whole of the disease, symptoms of meningitis being absent, and the meninges being free from gross lesions on examination post mortem. Even more constantly than in the supracute type is a blood culture positive; but the course of the disease is too rapid to admit of a diagnosis by this method during life.

4. **MILD TYPES.**—These cases are said to be common during the decline of an epidemic. It is at present quite impossible to say with what frequency they occur, because it is certain that many of them are overlooked. They are often treated as cases of "influenza," owing to the resemblance they bear to that disease. Many cases of acute fever with headache and pains in the back and limbs are regarded as "influenza" from a diagnosis by exclusion. They are not subjected to a lumbar puncture because the condition does not seem sufficiently grave. And if they recover from an illness of a few days' duration this is thought to be confirmatory of the diagnosis. In the presence of an epidemic of cerebro-spinal fever, however, a very close scrutiny of these cases should be made, and if there is even doubtful neck-rigidity or Kernig's sign, the cerebro-spinal fluid should be examined. Even when lumbar puncture is not at first decided upon a swab from the nasopharynx should be investigated for the meningococcus.

During an epidemic a patient who presents the symptom-complex of headache, malaise, pains in the back and limbs, slight fever, and some stiffness of the neck is probably suffering from a mild grade of meningococcus infection, and should be treated as such, by a lumbar puncture and the administration of serum. Subsequent measures will be determined by (a) the course of the disease; (b) the result of the examination of the cerebro-spinal fluid; and (c) the result of the examination of the naso-pharyngeal swab. The value of these cautionary measures is sometimes made apparent by the patient becoming rather suddenly worse after a few days, when it may be quite obvious that the nature of the disease is what was originally suspected.

5. POST-BASIC MENINGITIS OF INFANTS (CERVICAL OPISTHOTONOS OF INFANTS).—These cases were first described (1878) by Gee and Barlow. These observers recognised that they were dealing with a specific disease which had no causative association with tuberculosis, syphilis, or rickets. At the time of these authors' observations no epidemic of this type of meningitis had been described, and the cases were thought, even by much later writers, to be met with in sporadic fashion only. Of recent years, however, it has been recognised that this clinical manifestation of meningococcus infection may occur in epidemics.

The characters of the micro-organisms present in these cases were originally thought by some workers to differ from those of the micro-organisms found in the acuter cases occurring in epidemics. This distinction has disappeared of late, and there is more or less consensus of opinion that, although the strain may vary, the causative diplococcus is essentially the same in the acute as in the chronic, and in the epidemic as in the sporadic cases.

Seeing that the clinical features, again, do not differ materially in this type of meningitis from those often seen in cases occurring in older children, and occasionally even in adults, nor from those often seen in infants at times of an epidemic, it follows from these considerations that the inclusion of cases of post-basic meningitis in a general account of cerebro-spinal fever is amply justified.

Post-basic meningitis occurs chiefly in infants between the ages of 6 months and 2½ years. The same type of the disease may, however, be seen in children up to the age of 4 or 5 years. The onset is usually sudden, with a convulsion in many cases, and very frequently vomiting. The temperature rises abruptly, but does not, as a rule, remain high. In most cases the fever has become slight, or is absent, by the end of the first week of the illness. A large number of the patients suffering from the disease are therefore without fever when they come under observation.

The main and characteristic sign of the disease, the retraction of the head, becomes marked about the third or fourth day. It usually persists, with increasing severity, throughout the whole course of the disease. With it the back becomes arched, so that in extreme instances the occiput and the sacrum may meet. The extremities are usually in a condition resembling tetany, the stiffness being persistent rather than paroxysmal. Progressive wasting is another constant feature, and the degree of emaciation is often very considerable and very rapid. Of the other symptoms vomiting is one of the most common, and may be very troublesome. The pulse and respirations are usually frequent, and may be irregular.

The disease in most cases quickly enters upon a chronic course. The

infant lies motionless in its characteristic attitude for hours at a time, but is not usually comatose. Feeding is not as a rule difficult. The pupils are fully dilated. Blindness is present sooner or later in 30 per cent. of the cases (Langmead), the origin of the condition being central, since papilloedema of any magnitude is quite uncommon. Blindness is rare in the cerebro-spinal meningitis of older children and adults.

Lumbar puncture yields similar results to those found in the ordinary type of the disease; but, as the condition progresses, it is found that the meningococcus fails to appear in the fluid, and the polymorphonuclear cell-content changes to lymphocytosis, indicating the chronic stage of the infection. Dry punctures are not uncommon, indicating the probable closure of the foramen of Magendie by the plastic exudate at the region of the bulb and fourth ventricle. Fluid removed from the ventricles during life, or the examination of fluid found in the ventricles post mortem at this stage, often reveals the meningococcus, showing that the disease is still, in its chronic phase, to be regarded as a persisting infection. Indeed, *the post-basis meningitis of infants is probably to be considered as a meningococcus infection of the pia-arachnoid system with a special tendency to involve the cerebral ventricles by ependymitis*. The peculiar symptoms and course of the disease are thus explained.

Owing to the early development of hydrocephalus in this type of the disease, and the elastic nature of the infant's skull, the head enlarges in all directions, with bulging of the fontanelles and opening of the sutures between the bones. The shape of the skull thus approximates to that of congenital hydrocephalus. The eyes are turned downwards, and the sclerotics above the cornea are exposed by retraction of the upper lid. If this condition of acquired hydrocephalus has lasted for some weeks, there may be enlargement of the superficial veins about the nose and orbits, and running over the temporal regions to the vertex.

The mortality in this type of the disease is very high, probably over 80 per cent. Some of the cases linger for many weeks, and a few very gradually recover, with, all too often, residual blindness and also perhaps deafness. But the majority succumb to the intracranial pressure effects produced by the distended ventricles, in from 4 to 6 weeks from the onset of the disease.

Complications.—1. **HYDROCEPHALUS** may arise soon after the onset of the disease, or it may develop, and often rather suddenly, during its course, or it may be the final anatomical expression of the infective process, the counterpart of the symptom-complex seen in the chronic state of the disease. Certain symptoms are specially suggestive of the condition: pallor, cyanosis, increased frequency of the pulse with diminution in its tension and volume, shallow respirations, and stupor or coma supervening rather suddenly upon a previous state of consciousness.

If hydrocephalus arise at a later period of the disease than the end of the first week it may show itself with surprising suddenness, and sometimes in patients who seem to have been improving satisfactorily. In addition to the symptoms just enumerated, there is a recrudescence of the headache, vomiting and fever, which may have to a large extent subsided. More often it appears gradually and concomitantly with the progressive cachexia of the chronic type of infection. A valuable sign of its presence in children and adults is the presence of a resonant note to percussion over the anterior

horn of the lateral ventricle (Macewen). This sign is best obtained by placing the head in an upright position and inclining it to one side. The sign is not present in infants in whom the fontanelles are still open.

Hydrocephalus of the chronic stage of the disease is seen very constantly in infants suffering from the post-basic type of infection. Emaciation is a constant feature. The child lies for hours without stirring. There may be reiterated automatic acts, such as the biting of nails or the loosening and pulling out of teeth. The patients are rarely comatose. Vomiting and convulsions may occur.

2. PSYCHIC DISTURBANCES.—These are not very common, if the delirium and stupor are excluded. But the delirium may develop into mania, urged thereto by the violence of the headache. During convalescence it is not very uncommon to observe temperamental changes, such as puerility or emotionalism, which rarely persist for very long. Secondary dementia is, however, not unknown.

3. MOTOR DEFECTS.—Cranial nerve palsies are very uncommon. There are three groups of paralytic complications, but none of them is common.

(a) *Hemiplegia* and, less often, *monoplegia* of cortical type. This usually appears at the height of the disease, and is generally of temporary duration.

(b) *Flaccid paralysis* localised to one extremity or to a part of one extremity. The tendon-jerks are lost. Muscular atrophy may ensue, and R.D. may develop. The prognosis for the limb is by no means bad, and complete, or almost complete, recovery is probable.

(c) *Spastic ataxia*.—It is not uncommon to find convalescent patients very unsteady on their legs when they first begin to walk. Little children often refuse to walk at all for a time, even if they had learnt to do so before the illness began. Older children sprawl about the floor. Adults tend to topple over in an indiscriminate manner. In the majority of these cases there are no signs of organic disease, and the return to a normal gait is usually only a matter of time. In a few of the cases, however, the ataxia is accompanied by exaggerated knee-jerks, true ankle-clonus and extensor plantar response: a state of spasticity. The sphincters are intact, and there is no anaesthesia or analgesia. According to Sophian, who drew attention to these cases, the pupils often remain dilated, with a sluggish light reflex. Recovery, though slow, is the rule.

4. SPECIAL SENSES.—Complications involving the eye are very variable, and yet, in relation to the essentially nervous character of the main lesions of the disease, they are not very common. Fortunately, with the single exception of that form of blindness so often seen in the recovered cases of the post-basic type of the disease, very few of the eye complications are permanent. Inflammatory lesions include conjunctivitis, keratitis, iridocyclitis and (rarely) cellulitis of the orbit. Nervous lesions include extrinsic ocular defects which are not uncommon, but are generally transitory (*i.e.* spasmodic). Amaurosis is relatively common in the post-basic infection of infants; it is fortunately unusual in the more acute infection of children and adults. It is in most cases unaccompanied by any changes in the optic disc, and is therefore to be attributed to cortical changes associated with hydrocephalus. In some cases, however, a state of secondary optic atrophy is present. Optic neuritis is not a common complication; but papillitis, or a lesser degree of change even than this, is said by French authors to be extremely common.

The chief complication affecting the ear is meningitic deafness. This is a common and very serious complication, serious because when it occurs it is apt to be permanent. The auditory defect generally begins early in the course of the disease, and usually before the end of the first week. It is usually bilateral, which adds to the seriousness of the trouble in the event of its becoming permanent.

5. **ARTHROPATHIES.**—A certain degree of painful stiffness, and even swelling of the joints, is not at all uncommon as a transitory symptom in cerebro-spinal fever. Occasionally, however, one joint shows evidence of much more intense infection, becoming red, swollen and very painful with the slightest movement. It may suppurate, and secondary infection may occur.

6. Other complications are the broncho-pneumonia already referred to in little children; occasionally pneumonia in adults; and enteritis.

LUMBAR PUNCTURE.—In any suspected case of meningitis a lumbar puncture is as clearly indicated as is puncture of the chest in a suspected case of pleuritic effusion, or a blood-count in a suspected case of leukaemia.

If the patient is an infant, it can easily be held in the position about to be described by the nurse or assistant. In an adult free from delirium a local anæsthetic (novocain and adrenalin injection or, less suitably, ethyl chloride spray) is indicated. In stuporose or comatose patients the question of anæsthesia does not, of course, arise. In all other types of patient than these three a general anæsthetic is advisable.

Special apparatus is unnecessary. A long, stout needle with a syringe may be used. But nothing is quite so useful as a "**Barker's needle**," which is strongly made, and is fitted with a stylet, the point of which is bevelled off flush with the point of the needle, whilst the other end of the stylet terminates in a broad expansion to fit against the palm of the hand. The needles--it is advisable to have a duplicate one handy--are sterilised by boiling, whilst the patient is being prepared.

The puncture should be made with the patient in the recumbent position; even in adults who are not acutely ill no exception should be made to this rule. If the operator is right-handed, the patient lies most conveniently on his right side, and close to the edge of the bed. *A good light upon the back, without shadow from the operator's hand, is imperative.* The shoulder is on the bed and not on a pillow, so that the spine lies straight in its long axis. The knees are drawn well up to the abdomen, and the head and shoulders are bent forward; the trunk is thus arched with its convexity backwards. This position is best secured in an infant by one arm of the nurse or assistant being placed round the neck and the other arm under the knees. By clasping hands the infant's body can be brought into the desired posture. The skin in the situation of the sacrum and lumbar spine is now rubbed thoroughly with acetone or alcohol, or is swabbed with tincture of iodine.

The space between the third and fourth lumbar vertebra is the most convenient one for the puncture. (But the interspace above or below the **third** may be utilised with almost equal advantage.) This space is cut by a straight line joining the summits of the iliac crests. The most useful landmark is the spine of the fourth lumbar vertebra, which is the one lying nearest to this intercostal line. The puncture is made between this spine and the one lying next above it, which is felt at a distance of a $\frac{1}{2}$ to $1\frac{1}{2}$ inch

according to the patient's age. *It is essential to success to outline the two spines beyond any doubt.*

The puncture is made in the middle line and directly forwards. In adults it is sometimes found better to direct the needle slightly upwards. If obstruction be encountered this is probably by bone. The needle should be withdrawn a very little way and redirected slightly, with a view to correcting any fault which may be suggested by a revision of the surface markings. As soon as it is judged from the "feel" of the needle that it has entered the sub-arachnoid space, it is advisable to test its position before pushing it further forward. In this way the operator avoids piercing the venous plexus which lies at the opposite side of the canal, and which forms the common source of the blood that occasionally flows and obscures the result of the puncture. If such an accident happens it will often be found that slight traction on the needle in the direction of its handle will result in a flow of fluid free from blood; in this case the fluid should now be collected in a separate vessel.

If a "dry" puncture results, it is because the needle has not entered the canal at all, or has struck a nerve root which blocks its orifice, or because the inflammatory exudate is too thick to flow through it. The first possibility is the most probable, especially with an operator who is not very experienced.

Assuming Barker's type of needle to be used, the first 3 or 4 c.c. of fluid are allowed to run into an ordinary clean test-tube and are utilised afterwards for chemical tests which will go far to establish the diagnosis by the bedside. A sterile bottle or test-tube is then placed to receive the rest of the fluid, care being taken to avoid contaminations from the air, hands, etc. The bottle or tube is carefully sealed and is sent forthwith to the pathologist. If it cannot be dealt with in the laboratory within two hours some arrangement must be made for keeping the tubes warm, as by wrapping them in cotton-wool and placing them in proximity to a hot-water bottle. In general it may be said that *the fluid may be allowed to run away until the rate of flow is reduced to one drop to each three or four seconds.* The needle is now withdrawn by a quick movement, the skin being supported by firm pressure with the thumb of the left hand. The minute hole is sealed by a small piece of gauze soaked in collodion.

THE CEREBRO-SPINAL FLUID IN MENINGOCOCCUS MENINGITIS.—1. *The pressure and the amount of the fluid.*—These are both increased. The amount of fluid which flows away before the normal pressure is re-established depends upon the pressure and the consistency of the fluid; it averages about 30 c.c.

2. *The naked-eye appearance of the fluid.*—Various grades of turbidity are met with, from very slight opalescence to a highly purulent exudate. The degree of turbidity varies with the stage of the disease at which the lumbar puncture is undertaken. In the invasion stage the fluid may be almost clear; in the acute meningitic stage the fluid shows marked turbidity; later, again, as the inflammatory phase passes, the fluid becomes clearer. The presence of blood probably always means that a vessel has been punctured by the needle. Some degree of clotting often takes place when the fluid is allowed to stand, filaments of fibrin appearing at the bottom of the tube.

3. *Chemistry of the fluid.*—The albumin is increased in amount: instead of the faint opalescence which appears on boiling and adding dilute acetic acid to the normal fluid, a definite coagulum is produced, and an opaque

ring appears when the fluid is poured gently on to the surface of strong cold nitric acid. A quantitative estimation of the albumin shows that it may be present to the extent of 0.2 or 0.3 per cent. The globulin is also increased, as demonstrated by adding one part of the fluid to five parts of a 10 per cent. solution of butyric acid in normal saline, boiling, adding one part of normal caustic soda, and boiling again: a heavy white coagulum is obtained (Noguchi's test).

4. *Cytology of the fluid.*—In the early or invasion stage of the disease there is a quantitative increase in the lymphocytic content, a fact which often escapes observation if the lumbar puncture be delayed. With the arrival of the acute meningitic inflammation the chief cell present is the polymorphonuclear, usually in large numbers. At the stage, therefore, at which most lumbar punctures are undertaken, the cell content is chiefly polymorphous (70 per cent. to 80 per cent.). Later, when the stage of chronic hydrocephalus ensues, the lymphocyte again becomes the dominant cell, and in a much greater number than in healthy fluid. Most observers, however, describe cases of undoubted meningococcus meningitis in which the cell content is chiefly lymphocytic throughout. In the post-basis type of the disease the cells are most often lymphocytes for the greater part, and the same may be said of cases which are in a chronic stage whilst under investigation, whether the chief seat of the effusion be at the root of the bulb or elsewhere.

5. *Bacteriology of the fluid.*—Films made direct from the cerebro-spinal fluid, or, better still, from the centrifugised deposit, show intra- and extra-cellular meningococci in the great majority of cases at some time or other in their course. If a careful search be made and no cocci are discovered, it must not be assumed that none are present until the device of incubating the fluid as a whole is undertaken, and until cultures made upon suitable media are found to be sterile. The number of cocci seen, and their disposition with regard to the cells of the exudate, are matters of great variability. These things depend in the main upon (a) the stage of the disease, (b) the intensity of the infection, and (c) the influence of specific serum treatment.

Diagnosis.—The chief difficulty lies in not suspecting the presence of the disease. It is, of course, much more easy to bear in mind the possibility of cerebro-spinal fever during the presence of an epidemic than at other times. Cases which go undiagnosed, at least during the first part of their course, are those sporadic cases which generally happen to be atypical.

The reason why it may not be possible to decide on clinical grounds whether meningitis is present or not is because several infective processes, other than that due to the meningococcus, are apt to produce symptoms highly suggestive of meningeal irritation. This state of meningeal irritation, when due to toxæmia and not due to actual meningitis, has been termed *meningism* or *meningismus*. The question whether such a state is entirely toxic, or whether it is due to definite though slight changes in the meningeal tissues which just stop short of an inflammatory exudate, is problematical.

The diagnosis of cerebro-spinal fever may be conveniently considered under three heads—(1) from various acute infective processes with toxæmia, leading to "cerebral" symptoms; (2) from certain acute cerebral diseases of primary origin; (3) from other forms of meningitis.

1. **THE DIAGNOSIS OF MENINGITIS FROM TOXAEMIA MERELY.**—The question is settled partly by the clinical data and partly by an examination of the cerebro-spinal fluid. In a case of fever with "head symptoms," the following differential points should be borne in mind :

(1) *If headache and delirium synchronise, meningitis is probably present, and not merely toxæmia.*—Contrast an ordinary case of typhoid fever (toxæmia), in which headache and delirium alternate, the patient being free from pain when he is delirious, with cerebro-spinal fever (meningitis), in which the patient's headache and delirium are both present at the same moment.

(2) *Vomiting.*—If this occurs not merely at the onset of the fever, but on subsequent days also, at a time when the invasion period of the infection may be said to be passed, it is evidence of meningitis.

(3) *Pulse and respirations.*—Irregularities in rhythm are in favour of meningitis, and so is a relatively low pulse rate in comparison with the height of the temperature, provided typhoid fever can be eliminated.

(4) *Stiffness of the neck* without signs of otitis, enlarged glands, or of other local inflammation, even though it only exists in slight degree, is strongly in favour of meningitis. If the stiffness increases, rather than diminishes, with prolongation of the examination, the presumption is still greater.

(5) *Kernig's sign*, provided the patient is over 2 years of age, may be taken as being of equal significance with stiffness of the neck.

(6) *Papilloedema*, though its presence is much in favour of meningitis as against toxæmia merely, is not of much value in this connection, because it is usually absent at the early stage of the disease when the diagnostic problem requires urgent solution.

These six points are worthy of the most critical investigation. All other clinical features that may be present are equivocal—they may be produced by a toxic state of the brain or meninges. This statement refers to the state of the pupils, whether contracted or dilated ; the presence of *tâches cérébrales* ; the absence of the superficial or of the deep reflexes ; the "peevish" state of the patient with a resistant attitude ; marked insomnia or persistent stupor.

(a) *Influenza.*—This probably gives most difficulty in actual practice. *It should be noted that cerebro-spinal fever is very often mistaken for influenza, whereas influenza is rarely mistaken for cerebro-spinal fever.* The reason for this lies in the fact that the diagnosis of influenza is too often by exclusion. Fever prolonged past the seventh day, in the absence of an inflammatory focus (bronchitis, pneumonia, pleurisy, sinusitis, etc.), is unlikely to be due to influenza, and should therefore lead to a critical revision of the diagnosis.

(b) *Typhoid fever.*—The onset of the illness is nearly always a gradual one, and the evolution of the toxic symptoms is much more deliberate than in cerebro-spinal fever. This is perhaps the most significant differential point clinically. The leucocyte count is very helpful, and may prove of great diagnostic assistance before Widal's test is available : the count is low in typhoid (2000 to 7000), but it is high in cerebro-spinal fever (15,000 to 40,000). The rose spots of typhoid do not appear until the eighth or tenth day, whereas the rash of cerebro-spinal fever which might be confused with these usually appears much earlier. If the spleen is palpable in cerebro-spinal fever this is the case early, whilst the disease is at its "septicaemic" stage ; in typhoid

the spleen can rarely be felt before the end of the first week. The dissociation of headache and delirium in *toxæmia* already referred to is strikingly seen in typhoid fever. Moreover, the disappearance of the headache altogether, which occurs so frequently in typhoid fever after the tenth day, is another point of distinction; although its severity may diminish, it is rarely absent so early in the course of cerebro-spinal fever. As soon as a positive Widal test is obtained (usually about the seventh to tenth day), this finding, together with a leucopenia, may be relied upon as decisive in favour of typhoid. A positive blood culture may often be obtained before the agglutination test is available.

(c) *Pneumonia*.—Acute pneumococcus infection is the most common cause of a *toxæmic* state leading to meningism; the patient is usually a child, but not always. The symptoms of meningeal irritation may precede the signs of pulmonary disease, in which case the diagnosis can only be settled by lumbar puncture, or they may concur with such signs, in which case some care must be exercised lest the case be one of cerebro-spinal fever ushered in by pneumonia. Here the leucocyte count is of no help, for there is a high leucocytosis in pneumonia as in cerebro-spinal fever. A blood culture may reveal pneumococci, or a lung puncture may yield direct evidence of the nature of the infection; but if the diagnosis is considered in serious doubt, it will probably be deemed wise to perform lumbar puncture.

(d) *Measles*.—The differential diagnosis between this disease and cerebro-spinal meningitis does not appear to be a matter of practical difficulty. But in the writer's experience, although no reference is made to the fact by authors, it is sometimes necessary to decide whether or not a mixed infection is present. There is good evidence that acute encephalitis may occur as an immediate sequel to measles.

(e) *Malignant small-pox*, on the authority of Milligan, simulates cerebro-spinal fever very closely, on account of the sudden onset, headache, vomiting and pain in the back. But as the eruption occurs on the third or fourth day the diagnosis is not left long in doubt.

(f) *Rheumatic fever*.—If cerebro-spinal fever begins with arthritis and profuse acid sweats, if the patient is an adolescent, and if the pains are specially referred to the joints, the diagnosis of rheumatic fever is at first pardonable. The addition of an erythema makes the simulation all the closer. The failure of salicylates to relieve the pain, or to reduce the fever, should at once arouse suspicion. The important distinction between early rigidity of the neck in meningitis and rheumatic stiffness—that the former tends to increase with examination, and the latter tends to decrease—should be remembered in this connection.

2. DIFFERENTIAL DIAGNOSIS OF CEREBRO-SPINAL FEVER FROM CERTAIN DISEASES OF THE CENTRAL NERVOUS SYSTEM.—The most important of these diseases sometimes introducing a difficulty is—

Polioomyelitis (infantile paralysis).—This disease, like cerebro-spinal fever, exists in epidemic and in sporadic forms. Of recent years there have been several small epidemics in England. Sporadic cases are very common. If the type of the disease is the usual one, little or no difficulty is introduced in diagnosis from cerebro-spinal fever, because the invasion or febrile stage is short and the degree of illness it involves is not great; it is quickly followed by the paralytic stage, and the real nature of the malady becomes manifest.

In the cerebral type of poliomyelitis, however—acute polioencephalitis—there may be considerable resemblance to cerebro-spinal fever, in that the patient often lies in a state of semi-stupor, and vomiting may occur and may persist for 2 or 3 days. It is, however, in the meningitic form of the disease that a real difficulty presents itself. There may be added to the headache and vomiting, pain and stiffness in the neck and spine, and even some degree of opisthotonos. Careful study of the cerebro-spinal fluid usually serves to differentiate the two diseases.

Meningism may occur in a child as the result of acute gastric or intestinal irritation, and especially as the result of *ascaris lumbricoides*.

3. DIFFERENTIAL DIAGNOSIS OF MENINGOCOCCUS FROM OTHER FORMS OF MENINGITIS.—(1) *Pneumococcus meningitis* is rarely primary; almost always it complicates consolidation of the lung, or pleurisy, or otitis media, or infection of the nasal sinuses. But when it occurs it is apt to be extremely acute, running a rapid course and nearly always a fatal one.

(2) *Streptococcus meningitis* usually complicates some infective process about the skull, and most often this is middle-ear disease or sinusitis. In the majority of cases some surgical procedure has been attempted for the relief of the primary condition.

(3) "*Influenzal*" meningitis is a term applied somewhat loosely. Recent knowledge imparted by lumbar puncture makes the diagnosis of influenzal meningitis impossible from clinical grounds alone. And it is a striking fact that those cases in which Pfeiffer's bacillus is isolated from the lumbar puncture fluid, with the exudate of an acute meningitis, and definite symptoms, are not usually cases in which influenza has been suspected, still less diagnosed.

(4) *Typhoid meningitis*.—A true infection of the meninges may occur in typhoid fever, but it must not be inferred that a patient necessarily has typhoid meningitis because the bacillus is grown from the lumbar puncture fluid. This may occur without clinical evidence of meningitis and without histological and chemical changes in the cerebro-spinal fluid characteristic of meningeal inflammation.

(5) *Tuberculous meningitis*.—This is by far the commonest form of acute meningitis and therefore deserves fuller mention. The most helpful points in a differential diagnosis from meningococcus meningitis are the following. Tuberculous meningitis is rarely so sudden in its onset, the meningitis symptoms being preceded by a longer period of malaise, which begins less abruptly than the invasion symptoms of cerebro-spinal fever. The temperature is seldom high, except as an ante-mortem event, the usual range being 99° to 101°. Retraction of the head is transient and ill-marked, or is absent. Photophobia is more common than it is in cerebro-spinal fever. In adults aphasia is often a common and an early symptom. True (paralytic) squint is common. The "peevish" condition in children is much more marked during the first week. In both children and adults the depth of the stupor after about the tenth day is much greater. The discovery of tubercles in the choroid is pathognomonic, but these lesions rarely appear before the third week of the disease, and are therefore not of much service for diagnosis. Some authors lay stress upon the presence of signs of tuberculous disease elsewhere in the body as assisting in the diagnosis, but this is, of course, not true. Except in the case of adults, and by no means always then, there are rarely any such signs. The leucocyte count affords no

differential help as from cerebro-spinal fever, a leucocytosis of considerable size (15,000 to 30,000) being present in tuberculous meningitis.

However high a degree of probability that a patient is suffering from meningitis may result from a general examination, confirmation of this view rests entirely upon the results of lumbar puncture. For three reasons it should not be deferred: it establishes the diagnosis that meningitis is present; it decides the nature of the infection; it is a valuable aid to treatment in the event of a positive result.

Prognosis.—The mortality in cerebro-spinal fever is undoubtedly higher in the epidemic than in the sporadic cases, if the post-basic meningitis of infants, in which the mortality is very high, be excluded. There are, however, no good figures upon which to base an estimate of mortality in the sporadic cases. In epidemics the mortality prior to the introduction of serum treatment was about 70 to 80 per cent. It has certainly been much reduced of late, though the efficacy of sera varies greatly in different epidemics.

The influence of age is noteworthy. The disease is extraordinarily fatal in infants (patients under 2 years of age). This statement holds good both for the post-basic cases which are so often subacute or chronic in character, and for the acute cases. The mortality is lowest between the ages of 5 and 10 years.

A fulminating form of onset is invariably bad, and the mortality in these cases is very high, if indeed it is not 100 per cent. In the cases with less vicious invasion symptoms, one or more of the following symptoms betoken a grave issue: early loss of consciousness, wild delirium, persistent insomnia, extensive hæmorrhagic eruption, cyanosis. Later in the course of the disease the worst sign is the appearance of hydrocephalus.

The degree of fever, the intensity of the headache, the amount of rigidity, the presence of marked emaciation, frequency and irregularity of the pulse, rhythmical respirations, the presence of herpes—none of these things yields any information of value in predicting the issue of the disease. *In few other diseases, if in any, is it possible for the patient to be so ill and yet to recover completely, as in cerebro-spinal fever.*

The state of the cerebro-spinal fluid in relation to prognosis is to a high degree equivocal. No reliance must be placed upon it except for purposes of diagnosis. It may be almost clear and may contain very few meningococci, and yet the patient may be desperately ill and likely to die. On the contrary, it may be highly purulent and crowded with meningococci, and yet the patient may get rapidly well.

According to Netter and Debré, the most important fact bearing upon prognosis is the stage in the disease at which serum treatment is begun. Flexner found that if serum was given between the first and third days, the mortality of the disease was reduced to 18·1 per cent.; if it was delayed until the seventh day the mortality rose to 36·5 per cent.

Treatment.—1. **PROPHYLACTIC.**—The principles governing prophylaxis are those applicable to infectious diseases in general. Although it would appear that the healthy carrier is more responsible for the spread of the disease than the patient himself, it is none the less important to isolate every case of the disease and to exercise all precautions against further contact with healthy persons. Whenever possible the patient should be transferred to a hospital, and preferably to an institution where the staff is accustomed to deal with infectious diseases.

All contacts who are found to be carriers should be placed under quarantine, and should be kept there until the naso-pharynx is free from meningococci. The carrier should live as far as possible in the open air. For lavage of the naso-pharynx, and for a gargle, a weak solution of izal may be used, or peroxide of hydrogen, or a 1 : 1000 solution of permanganate of potash, adding 1.5 per cent. of sodium sulphate to assist penetration (Gordon). For spraying the nose or fauces, a 1 per cent. solution of iodine with 2 per cent. of menthol in parolein may be used.

The use of a meningococcus vaccine for the purpose of clearing the throat has not proved to be successful.

2. CURATIVE.—(1) *Serum treatment*.—Cerebro-spinal fever is not only a specific disease in regard to its aetiology, it is specific also in regard to its therapeutics. Given that treatment by an appropriate anti-meningococcus serum is early and thorough, the disease is curable in the large majority of cases.

It is of vital importance that the first dose of serum be given at the earliest possible moment after the disease is diagnosed or is strongly suspected. Nothing in the treatment of the patient should take precedence of this first serum administration. If the result of using one brand of serum in a particular case is unsatisfactory, a different brand should be tried, and even a third, if necessary. It may even be advisable to prepare a special serum for the case of a particular epidemic.

The serum must be given by the intraspinal route; it has much less therapeutic value in the ordinary type of case if given intravenously, and perhaps little or none if given subcutaneously.

The serum may be allowed to flow into the spinal theca by gravity, or it may be injected by means of a serum syringe. The rapid injection of serum is harmful and may even lead to a fatal result; but it is doubtful if the injection method is prejudicial, provided due care be exercised to warm the serum and to inject it very slowly.

With regard to repetition of the serum, Flexner laid down an arbitrary rule for guidance on this matter, recommending the use of serum daily for 4 or 5 doses, and advising that after this the practitioner should be influenced by the subsequent clinical condition of the patient and by the state of the lumbar puncture fluid at successive operations. Some such custom as this remains the usual one in the ordinary type of the disease. It is desirable to vary this rule in individual cases.

If the case is of the superacute type, it is well to repeat the dose of serum in 8 to 12 hours and again after the same interval. In this way an effort is made, consistent with the precautions already referred to, to get as much serum as possible into the cerebro-spinal sac during the early stages of the disease. After these initial 3 doses an interval of 24 hours may be allowed to pass before the next dose is given.

If the case is a mild one the original serum administration need not be repeated for 24 hours, and the second interval may be 48 hours, provided the course of the disease is satisfactory. Although in very mild cases one administration of serum with the drainage it entails is often sufficient to establish a definite and lasting improvement, this must never be depended upon, as recrudescences are common and are certainly preventable by adequate use of the serum.

No doubt the best indication for the repetition of the serum is the condition of the meningitic exudate as seen at successive punctures. The lumbar puncture fluid should always be examined by a competent observer whenever this is possible. The indication for further serum is proportionate to the number of meningococci still present in the extracellular form. But it is not often practicable to prepare a stained film of the fluid straightway so as to be guided by the result. The decision whether to use serum or not must in most cases be determined by a consideration of the clinical condition together with the naked-eye characters of the fluid. In regard to the latter it may be said that if the fluid is still turbid (indicating the presence of polymorphous cells), it is well to give more serum. If serum is not given upon the occasion of any puncture, and the pathologist reports extracellular cocci in the specimen examined from that particular puncture, this should decide the practitioner to give serum at the puncture next undertaken, whatever the naked-eye features of the fluid may be.

(2) *General management*.—The diet is to be adjusted to the patient's condition. The disease is an exhausting one, and as full a dietary as is consistent with the state of the digestive secretions is to be allowed. If the fever is a conspicuous feature, and the patient is drowsy or delirious, the mouth is usually dry; the diet is then necessarily restricted to fluids, which should be given in the form of diluted milk, and freshly prepared meat essences, in small quantities at frequent intervals. Water should be given freely. If the patient is in a state of stupor the act of swallowing must not be relied upon; feeding must then be by the passage of a nasal tube three or four times in the 24 hours. According to the age of the patient, from 5 to 10 ounces of citrated milk and water (equal parts), or of peptonised milk, or of beef essence are allowed to run into the stomach from a funnel attached to the tube and held at the necessary height above the bed. A raw egg may be beaten up in the milk and a little brandy may be added if the state of the heart indicates the use of alcohol. If vomiting is troublesome, peptonised milk should only be used, or whey or albumin water. If this symptom is persistent, it may be advisable to put no food at all into the stomach for 24 to 48 hours, relying upon saline injections (5 to 20 ounces according to age) per rectum every 6 hours, supplementing these, if thought desirable, by the subcutaneous use of a 10 per cent. solution of dextrose in normal saline.

The bowels are usually constipated; it is therefore frequently necessary to use purgatives: castor-oil or calomel followed by a saline, or compound liquorice powder. If the patient is comatose early in the disease, when treatment is beginning, it may be advisable to give 2 minims of croton oil in butter or moist sugar.

Urinary difficulties do not usually occur unless the patient is unconscious, in which case it is important to bear in mind the possibility of retention, which may lead to "overflow incontinence." This condition indicates the use of the catheter, with the customary care in the matter of asepsis.

(3) *Drugs*.—It is exceedingly doubtful if any drug exercises a beneficial influence upon the infection, but urotropin, in full doses (60 grains daily), has been recommended, and has experimental evidence in its favour.

(4) *The treatment of certain symptoms*.—Headache is usually the most distressing symptom calling for special treatment. In all but the mildest cases of the disease it is a good thing to shave the scalp and to apply an

icebag or Leiter's tubes. A leech over each mastoid is sometimes followed by relief for several hours. If, as is often the case, the pain is referred to one particular spot, the leech should be applied there. Drugs are not of much use in controlling the very severe headaches, but antipyrine, caffeine, and aspirin may all be tried in full doses. Morphine may be imperative in some cases, because nothing else may be of any service. Restlessness, delirium and insomnia,—if these symptoms are troublesome a trial should be given to some such combination as the following :—

R Ammon. bromid., grs. x-xxx.
 Tr. valerian. ammon., ℥x-xxx.
 Syr. chloralis, ℥xx ʒij.
 Aquam ad ʒi.
 S.—Secundis horis ad doses iv-vi.

The pains and the stiffness are best treated by warm baths at a temperature of 102° to 104° F.

If the delirium is exhausting or the condition verges upon mania, vapour of chloroform may be used, or morphine with atropine may be given. Hyoscine should be avoided.

Arthritis.—The affected joint is best treated by fixation, by the application of hot stupes, and by aspirin internally. If the fluid effusion becomes considerable, or does not quickly yield to these measures, the joint should be aspirated and 5 to 10 c.c. of serum should be injected into it if the meningococcus is demonstrated in the fluid.

(5) *The repetition of the lumbar puncture.*—A lumbar puncture of necessity precedes each intraspinal dose of serum. But there arises in many cases an indication for continuing the lumbar punctures over a longer period than that covered by the serum administrations. Any further untoward event in the course of the disease, or any undue prolongation of it, is best met by repeating the puncture. The amount of fluid withdrawn is determined by the amount present, and its characters. Too much is not likely to be withdrawn. If the temperature rises after having settled for 2 or 3 or more days ; if there is an exacerbation or a recurrence of the headache, restlessness, delirium, or insomnia ; if rigidity returns after an initial subsidence—in either of these instances it is advisable to investigate the pressure and the characters of the cerebro-spinal fluid. There are reasons for thinking that further drainage at certain intervals tends to prevent the development of the most serious of the complications of the disease, a state of hydrocephalus. It may therefore be necessary to repeat the puncture several times, especially in the most chronic cases and in the group of post-basic cases in infants.

(6) *Treatment of hydrocephalus.*—If a condition of hydrocephalus has been diagnosed, it is advisable to tap the lateral ventricles and to inject serum. This procedure is not so difficult nor so dangerous as may be supposed.

(a) The patient is usually an infant with open fontanelles. The region of the anterior fontanelle is shaved and the skin is sterilised. A stout needle, to which a syringe can be attached, is inserted at the lateral angle of the fontanelle, and is gently pushed towards the mesial line for a distance of an inch or an inch and a half. The fluid is usually under considerable

pressure, so that it becomes quickly known when the needle reaches it. It is not necessary or advisable to attempt to withdraw more fluid than comes into the syringe with very gentle aspiration. With great care, an amount of serum less in bulk than the fluid withdrawn is now introduced into the ventricle.

(b) In older children and adults the operation of decompression becomes necessary; and here again, though a much more serious procedure, the practitioner should not hesitate to give the patient the benefit of the operation and of the use of serum by this special route.

THOMAS HORDER.

PLAGUE

Definition.—Plague is an acute infectious disease, running a rapid course, associated with high fever, high mortality, generally with enlargement of the lymphatic glands, and due to a specific micro-organism—the *Bacillus pestis*.

Ætiology.—The disease may occur anywhere, but is more common in subtropical regions. Towards the equator it tends to die out. All races and ages are subject to it. It is due to a bacillus, a short rod, often distinctly oval-shaped, and with somewhat rounded ends. It is non-motile, Gram-negative, and when suitably stained shows characteristic bipolar staining. The bacilli measure from $1\ \mu$ to $1.5\ \mu$ in length. Growth takes place easily on all the ordinary culture media. The disease is common in the rat, and epidemics amongst these rodents often precede the human cases. The germ is spread from rat to man, in ordinary bubonic cases, by the common rat flea (*Xenopsylla cheopis*); but in pneumonic cases the transference is direct by droplets of sputum, and persons suffering from chronic pulmonary troubles are specially liable to the pneumonic form, which is intensely infectious from person to person—doctors and nurses often acquiring the disease.

Pathology.—The mild forms may be due to attenuated brands of bacilli. The plague bacillus gives off a toxin, and this is responsible for many of the lesions present. The severity of the toxæmia is seen in the hæmorrhages and the general changes in the viscera. In bubonic plague the bubo is apparent. Marked features are met with in the lymphatic system—all the glands of the body being more or less affected. Even in pneumonic and septicæmic plague, where there is no primary bubo, enlargement of the glands is evident at autopsy. The primary bubo is characterised by its marked hæmorrhagic nature, the individual glands being matted together and the periglandular tissue infiltrated with a blood-stained gelatinous fluid. Bacilli are present in the necrosed tissue in enormous numbers. In the secondary glands, the periglandular infiltration is absent, and the hæmorrhagic character is not so marked. On section, these glands appear greyish-red. Bacilli are no more numerous in them than in the blood and spleen.

The heart often shows dilatation of the right side, with its muscle soft and fatty, and petechial spots on the epicardium; the liver is enlarged and congested with cloudy swelling and fatty changes of the parenchymatous

cells; the spleen is also enlarged, the pulp soft and hyperæmic; the kidneys are congested with cloudy swelling and early fatty changes.

Hæmorrhages, varying from petechial spots to larger collections of blood, are always present; they are seen under the skin, in the subcutaneous tissues, and on the serous membranes. The name "black death" was derived from these hæmorrhages.

In pneumonic plague the lesion is that of a broncho-pneumonia, areas of consolidation with hæmorrhagic effusions being scattered throughout the substance of the lungs. Bacilli are present in the lesions in large numbers.

Recently Norman White has suggested that the plague bacillus alone does not cause epidemics of pneumonic plague. He believes there is an additional organism at work, working in symbiosis with the plague bacillus, and that pneumonic plague is a disease *sui generis*. This idea has been criticised by C. A. Gill and others.

Symptoms.—Plague may be differentiated clinically into seven types—(1) Bubonic; (2) Septicæmic; (3) Pneumonic; (4) Intestinal; (5) Cerebral; (6) Cellulo-cutaneous; (7) Abortive or ambulatory (*Pestis minor*).

1. *Bubonic*.—The incubation varies from 2 to 5 days. The onset is sudden, with high fever, often ushered in with one or more rigors; the pulse is rapid, and severe constitutional disturbances are present—severe frontal headache, giddiness, nausea, vomiting, diarrhœa, with pronounced bodily weakness and mental terror. The patient may, on walking, reel like a drunken man.

The bubo appears on the second or third day, the glands rapidly enlarging till they reach the size of a hen's egg. Pain may be severe. As a rule only one group of glands is affected, and 80 to 90 per cent. of these suppurate, the abscesses maturing during the course of the second week. Buboes occur in order of frequency in the inguinal, axillary, submaxillary and cervical groups.

The urine contains albumin, and the blood shows a polymorphonuclear leucocytosis. Death may take place at any time, but is commonest on or about the third or fifth day. If recovery take place, the severity of the symptoms gradually lessens; but convalescence is somewhat protracted. Sequelæ are common, such as sepsis, carbuncles, etc.

2. *Septicæmic*.—The disease runs a very rapid course, the symptoms being those of a severe septicæmia. The glands are usually slightly enlarged and tender; but no definite bubo is seen. The patient sinks rapidly and quickly dies. Blood may be passed per rectum towards the end.

3. *Pneumonic*.—The onset in this type is ushered in by a chill, followed by a rapid rise of temperature, with headache, dizziness, pains in the limbs, accompanied by pain and tightness in the chest, with cough and expectoration of a thin, sanguineous, watery fluid. The respirations are increased, with cyanosis, diminished resonance over one or more areas and rhonchi (Childe). Herpes labialis is said not to occur. Multitudes of plague bacilli, either in pure culture, or mixed with different cocci, are present. The condition resembles the severe types of influenzal broncho-pneumonia. Why some epidemics take on this form almost entirely is not clear, e.g. the Manchurian epidemic 1910–11.

4. *Intestinal*.—A rare form. Wilm described it in the Hong-Kong

epidemic of 1896 as follows: It runs its course without buboes; its predominant features being disorders of the intestinal canal, vomiting, incessant purging, liquid stools, bile-stained, with an offensive odour and often mixed with blood. Definite pathological lesions are seen in the intestine at autopsy.

5. *Cerebral*.—In this type the patient dies with cerebral symptoms closely resembling those of malignant malaria—delirium, convulsions and then a gradually deepening coma. Definite plague meningitis has also been described.

6. *Cellulo-cutaneous*.—Carbuncles due to the plague bacillus are sometimes encountered, and have to be distinguished from ordinary coccic carbuncles. The latter may, however, appear as a sequela in the disease. The plague carbuncles have a necrosed and ulcerated centre with a hard edge, from which a red areola spreads, sometimes covered by minute vesicles. Plague bacilli are demonstrable.

7. *Abortive or ambulatory (Pestis minor)*.—Cases of this sort are met with in all epidemics. The disease may be acute or chronic, during which—without serious indisposition or without fever—buboes develop, and these may suppurate or be absorbed (Scheube). Other abortive types have also been described—the glands of an area swell and become painful, there may be headache, fever, giddiness and indefinite pains, then everything clears up and the patient quickly recovers.

Prognosis.—The disease is a serious one, the mortality being as high as 80 to 90 per cent. in some epidemics.

Treatment.—The aim for the future sanitarian is to make houses, grain-sheds, and all other buildings rat-proof. If the rat can be kept from intimate contact with man, plague can be controlled. Destruction of rats should be carried out where possible. Ships and steamers can be disinfected by the Clayton process—sulphur gas. Vaccination should be urged upon those entering plague areas (Haffkine's method). The general treatment of the disease is symptomatic, no drug being of special value. Good results have been reported after large doses of perchloride of mercury and carbolic acid, and intravenous injections of tincture of iodine have also been given a trial. Stimulants should be used early. Buboes and carbuncles should be treated with hot fomentations of carbolic acid and sublimate. It is better not to excise them or open them before ripe, for fear of a general infection.

Serums have been tried (Anti-plague, Yersin's, and Lustig's). The general opinion is that these lower the death-rate in bubonic, but are useless in septicemic and pneumonic cases.

UNDULANT FEVER

Synonyms.—Malta Fever; Mediterranean Fever; Gibraltar Fever; Rock Fever; Neapolitan, Cretan, Cyprus, Danube, Levant Fever.

Definition.—An endemic specific fever, sometimes becoming epidemic, of long duration, with a tendency to long wavy relapses, due to the *Micrococcus melitensis*. The disease is common in the goat, and man generally acquires the infection by drinking milk from such animals.

Ætiology.—The fever is common on all the Mediterranean littoral; it

is also met with on the Red Sea, in Zanzibar, Uganda, Nigeria, and South Africa. In the East it is found in India, Assam, Hong-Kong and China; in the West, in the West Indies, Porto Rico, etc. Its distribution is probably even much more extensive. The indigenous population seems to have a certain immunity to the disease, e.g. Malta, the Maltese not suffering so much as the English soldiers and sailors. All ages and both sexes are equally affected.

The germ of the disease is a minute coccus, the *Micrococcus melitensis*, which is distributed throughout the body, in the blood, bile, faeces, urine and milk. Inoculations of the germ produce the disease, and there have been numerous instances of workers with the organism becoming infected. The disease is primarily one of goats, in which it apparently causes few symptoms; though the coccus is excreted in large numbers in their milk. When the infection is a severe one the milk may be of poor quality. Cases of undulant fever in South Africa have lately been shown to be caused by the *Bacillus abortus*, an organism closely resembling the *Micrococcus melitensis*. A *Micrococcus para-melitensis* is now also described.

Pathology.—The changes found at autopsy are those associated with high temperature and the circulation of toxins in the blood. There is no specific inflammation of Peyer's patches or the other glands of the intestine. The spleen is always enlarged, averaging about 20 ounces in weight. The mesenteric glands are slightly swollen. The lungs are congested at their bases and oedematous—pneumonia may also be present.

Symptoms.—The incubation period is usually stated at 14 days, but may last a longer or shorter period. Subcutaneous inoculation of monkeys gives an incubation period of 5 days, whereas if the disease result from ingestion this is lengthened to about 15 days.

Four varieties are usually described: (1) Ambulatory; (2) Ordinary; (3) Intermittent; (4) Malignant.

(1) *Ambulatory*.—Sometimes the symptoms are so slight that a patient can go on with his work. Out of 525 dock hands examined by Shaw in Malta, 79 gave positive serum reactions, whilst out of 22 of those specially tested 9 showed the organism, either in the blood or urine, or in both. These cases then approximate to definite carriers. In other cases there is slight fever, and other symptoms which quickly disappear. Serum tests show, however, these cases have been infected.

(2) *Ordinary or undulant type*.—The symptoms resemble those seen in other fevers; but the temperature chart is characteristic. Bouts of fever of 20 days' duration or so are followed by remissions, these alternating with each other and producing a series of undulations on the temperature chart.

The total duration of the pyrexia is 90 to 120 days, or even longer; some cases of a year have been described, and Bruce has even noted one of three years. In addition to the peculiar temperature, constipation is a prominent symptom, also pain and swellings in the joints. Neuritis and orchitis occur, the latter usually passing away quickly, but the former may persist and cause severe crippling. Sweating is seen during the remissions. The spleen is enlarged and painful. Bronchitis, congestion and oedema of the lungs with slight hæmoptysis are seen in some cases. Secondary anæmia eventually develops.

After running a more or less prolonged course, the remissions become more prolonged, the febrile exacerbations less high, and gradual con-

valescence is established. The neuritis and anæmia may persist for a considerable period of time. Marked debility is also common.

(3) *Intermittent type*.—Here the temperature swings up and down like a benign tertian malaria. Often about normal in the morning, it rises suddenly in the afternoon to 105° F. or higher, accompanied with chilliness or a definite rigor. By evening, the temperature falls again, associated with drenching sweat.

(4) *The malignant type of Hughes*.—The patient is attacked suddenly with high fever—severe pains all over the body, with signs of diarrhoea and pneumonia. Vomiting then sets in, and the patient gradually passes into the typhoid state; the temperature rises still higher, hyperpyrexia develops and the patient dies.

Diagnosis.—This has to be made from the other specific fevers. Clinically, undulant differs from typhoid and the paratyphoid fevers in its longer duration, the patient does not look so ill, rose spots are absent, constipation is the rule, and in the frequent occurrence of painful arthritic or neuralgic symptoms. The surest method for determining a diagnosis is by blood culture for the specific germ and by the melitin test. The agglutination test is also useful. Dilutions of 1-20, 1-100, and 1-500 should be used. It has lately been shown, however, that 20 per cent. of genuine cases of undulant fever do not agglutinate. Agglutinins, when present, may persist in the blood for long periods after the patient has recovered. If a suspicious case does not react to the ordinary *M. melitensis*, then tests should be tried with the *M. para-melitensis* as well.

Prognosis.—This is quite favourable as regards life and ultimate recovery, the death-rate being only from 2 to 3 per cent. Death occurs as a rule in the first week or two of the disease and is preceded by continued high temperatures, a tendency to hyperpyrexia, delirium, dry tongue and diarrhoea. In the chronic cases, there may be great debility, anæmia and emaciation. Neuritis is often troublesome and very difficult to remove.

Treatment.—Goat's milk should be rigidly excluded as an article of diet in places where the disease is rife. By this simple procedure, the disease has been stamped out of the Navy and Army in Malta, and cases are now of excessive rarity amongst the troops. If goat's milk has to be used, the agglutination test should be performed to determine if the goat be infected or not. Boiling the milk for 20 minutes renders it safe. Destruction of infected goats is also indicated. There is no specific drug. Symptoms have to be treated on ordinary principles. The tendency to hyperpyrexia in severe attacks must be borne in mind, and if it threatens sponging with ice water or cold baths will be required.

Sleeplessness, headache, arthritis and orchitis are all treated on general principles. The patient should be kept strictly in bed at first, but later on—especially if the weather be warm—it may be advantageous for him to sit in a bath-chair or even to go out of doors. This tends to prevent congestion and œdema of the lungs.

As regards food, the diet must not be too meagre, as the fever is a prolonged one. When the temperature is high, the diet may be restricted to fluids, but when normal, solids of a nourishing nature may be given, milk puddings, eggs and even fish. Vaccines have been tried, but so far have not given any very definite results.

G. CARMICHAEL LOW.

TULARÆMIA

Definition.—A plague-like general infection of rodents, hitherto confined to North America, communicable to man. The disease has the peculiarity, in which it resembles Malta Fever, of being extremely infective to laboratory workers handling the causative organism, *Bacterium tularense*, and attention to this aspect has been drawn by an important paper by Professor J. C. G. Ledingham and Dr. F. R. Fraser, in the *Quarterly Journal of Medicine*, vol. xvii., describing three cases occurring at the Lister Institute.

Ætiology.—In 1911 M'Coy, during plague work among ground squirrels in California, discovered a plague-like disease not due to *Bacillus pestis*, and in 1912 M'Coy and Chapin isolated the specific organism from the blood of infected animals, and it was named *Bacterium tularense*. Subsequently the organism was found in various rodents, and endemic centres of the infection have been recognised in many areas of North America. The first human case of infection appears to have been reported by Pearse in 1910, but bacteriological proof connecting it with *B. tularense* was provided by Francis subsequently. Where the infection is endemic among rodents, human cases are not uncommon, and possibly some have recovered unrecognised. The infection is conveyed from animal to animal by various blood-sucking parasites. The fæces of infected bugs have been shown to be infective. There is thus no difficulty in understanding how endemic centres of infection are kept up, and human infections in the field are readily understood. But it is difficult to explain the cases of infection in laboratory workers. It is suggested that a possibility is respiratory infection during the anæsthetising of experimental animals, when coughing is not uncommon, and the virus is certainly contained in bronchial secretions, as well as the excreta generally. The question appears to be parallel to the difficulty of explaining the great liability of laboratory infections with *Melitensis*.

B. tularense is a minute, Gram-negative, cocco-bacillus, measuring, according to M'Coy and Chapin, 0.3, 0.7 and 0.2 μ . It is not easily stained by the ordinary dyes, unless a mordant, such as carbolic or aniline, is added. It is refractory to growth on ordinary media, the original cultures being obtained on a medium composed of egg-yolk. It will grow readily on serum and blood agar, and glucose agar if a piece of rabbit spleen be added thereto.

Pathology.—In animals, nothing characteristic is found. At the site of inoculation some diffuse necrosis may be seen, and occasionally swelling of the corresponding lymph glands. The spleen, liver, lungs, and kidneys may show small necrosis areas. Human cases contracted in the field, probably from some blood-sucking fly, will show a local ulceration at the site of the bite, with swelling, and possibly suppuration, of the local lymph glands. Cases contracted in the laboratory provide no pathological data, for there is no evidence of the portal of infection, and the blood shows no characteristic changes.

Symptoms.—Sudden onset of fever, up to 103°, with marked malaise and no localising symptoms, in the case of laboratory workers with *B. tularense*, suggest the initiation of serological tests with specific antigen. The temperature subsided at the end of 3 weeks in the American series of cases, but it remained up for a longer period in the London series, and in one case there were irregular rises of temperature for a period of a year. The marked

features of the majority of the cases were the malaise, the recurrent nature of the fever, and the prolonged inability to work.

Diagnosis.—In endemic areas people handling rabbits and other rodents, who develop fever, with or without localising signs of insect bites, should be under suspicion. In this country, only laboratory workers could possibly be infected. In either case, the diagnosis depends upon specific agglutination to *B. tularensis* antigen. Very definite agglutinations were noted towards the end of the second week after the commencement of the disease, and the titre rose rapidly and remained high during the long convalescence.

Prognosis.—This appears to be of about the same order as that in Malta Fever. The disease is not fatal, but causes a long period of inability to work.

Treatment.—No account is given of any attempts to confer immunity, either prophylactic or phylactic, and the treatment would appear to be one aiming at rest, with measures to counteract the anæmia that tends to supervene.

JOHN MATTHEWS.
THOMAS HORDER.

B. THE MYCOSES

Numerous fungi are pathogenic to man, and the lesions caused thereby are conveniently described as the mycoses. The classification of these fungi is as yet somewhat confused, though five main families may be recognised. These with their chief genera and the lesions caused thereby are indicated in the subjoined table.

TABLE OF FUNGI PATHOGENIC TO MAN
(MODIFIED FROM BESSON)

Family.	Genera.	Causing
I. HYPOMYCECTIDÆ	1. <i>Discomyces</i> . (<i>Nocardia</i> .)	(a) Actinomycosis (b) Mycetoma.
	2. <i>Malassezia</i> .	<i>Tinea versicolor</i> .
	3. <i>Trichosporum</i> .	Trichosporosis.
	4. <i>Coccidioides</i> .	Dermatitis.
	5. <i>Sporotrichum</i> .	Sporotrichosis.
	6. <i>Oidium</i> .	(Thrush.)
II. MUCORACIDÆ	1. <i>Mucor mucedo</i> .	Pulmonary mucormycosis.
	2. <i>Mucor corymbifer</i> .	Auricular and pulmonary mucormycosis.
	3. <i>Rhizo mucor</i> .	Pulmonary rhizo-mucor-mycosis.
III. GYMNOASCIDÆ	4. <i>Rhizopus nigricans</i> .	Mouldy-food poisoning.
	1. <i>Trichophyton</i> .	The ringworms.
	2. <i>Epidermophyton</i> .	<i>Tinea cruris</i> .
	3. <i>Microsporum</i> .	Juvenile ringworm.
	4. <i>Achorion</i> .	Favus.
IV. PERISPORACIDÆ	1. <i>Aspergillus</i> .	Aspergillosis "Pinta."
	2. <i>Sterigmatocyetis</i> .	Otomycosis.
	3. <i>Penicillium</i> .	Otitis.
	4. <i>Lepidophyton</i> .	<i>Tinea imbricata</i> .
V. SACCHAROMYCETIDÆ	1. <i>Endomyces</i> .	Thrush.
	2. <i>Saccharomyces</i> .	Myxomatous tumours.
	3. <i>Cryptococcus</i> .	(a) Blastomycosis. (b) Histoplasmosis.

Some of the diseases mentioned in this table, for example the ringworms, are described in other sections. Six of them will be described here—actinomycosis, mycetoma, sporotrichosis, aspergillosis, blastomycosis and histoplasmosis, the lesions of which are of the nature of infective granulomata.

ACTINOMYCOSIS

Synonym.—Ray-fungus Disease.

Definition.—A local infection, tending to become general, due to the *Streptothrix actinomycetes*, producing granulomatous lesions chiefly in the jaw, skin, lung and digestive tract.

Ætiology.—*Actinomyces bovis* was first described by Böllinger in 1877 as the micro-organism producing large, hard, sarcomatous masses occurring about the jawbones of cattle, and in the following year Isaack and Wolff found the same organism in human cases.

The characteristic of the disease is a suppurative lesion, the pus from which contains visible granules which, examined microscopically, are seen to have a centre of a closely meshed filamentous network, with a border of radially arranged striations, often ending in club-shaped bodies. Formerly these club-shaped bodies were thought to be spores, but they are now regarded as hyaline thickenings of the sheaths of the threads. The clubs are only found in preparations made from pus from active lesions, or in cultures on media in which serum or blood is employed.

It is essential in examining suspected pus to isolate a granule. If granules be not readily detected in the wound or in the pus, Colebrook has pointed out that if pus be vigorously shaken in a tube of water the granules, not being emulsified, will sink to the bottom and may be removed by a pipette. Microscopical examination is very much facilitated by crushing the granules between two slides. The mycelial filaments retain Gram's stain, while the clubs lose it and take the counter-stain. Culture is in any case difficult, depending to a large extent on the amount of secondary infection. To eliminate this as far as possible the granules should be well shaken in a sterile saline solution, and then after crushing between sterile slides should be sown on to glucose agar plates which are incubated anaerobically, or crushed granules may be shaken up into melted glucose agar which is aspirated into long sterile tubes according to the method of Vignal. Numerous subcultures may be necessary to complete the isolation of the organism.

Mode of invasion.—Till recently the view has been held that actinomycosis was conveyed to cattle and man from vegetable sources. Colebrook, in a review of 28 cases coming under his observation, brings forward strong reasons for believing that the fungus may be present under normal conditions in the alimentary tract. He quotes Lord as finding similar organisms in carious teeth and tonsillar crypts, and himself found not dissimilar filamentous organisms in each of six carious teeth examined. He has also shown that the serum of heavily infected patients causes agglutination of suspensions of actinomycetes, as also does the serum of inoculated rabbits. The same observer supports the observation of Klinger as to the frequent association with actinomycetes bovis in actinomycotic lesions of a minute Gram-negative cocco-bacillus, to which Klinger gave the name of *Bacillus*

actinomyces *comitans*. The significance of the association is not known.

Symptoms.—These depend upon the anatomical distribution of the granulomata.

1. *The jaw and adjacent structures.*—When the infection occurs in these parts the patient presents a swelling very like a sarcoma, generally about the angle or ramus of the mandible. The swelling may, however, affect the sub-mandibular tissues and lymph glands rather more than the jaw itself, and one of the writers has recently seen a case in which the lesion was confined to the glands. The swelling is tender, somewhat painful, and not generally so hard as in sarcoma. It may show one or more spots of softer consistency than the rest of the lump. In most cases there is no obvious source of infection inside the mouth; the assumption is—in the light of observations quoted above—that the avenue of invasion is a carious tooth, or the gums and peri-odontal membrane.

2. *The intestines; appendicitis.*—The favourite site of infection is the cæcum and appendix region. The disease manifests itself either as an attack of appendicitis, most often acute, in which case the diagnosis is made only at the time of laparotomy; or as a slowly growing lump in the right iliac fossa, with some pain, tenderness, and constitutional disturbance, in which case suspicion may be aroused as to its nature, if it be remembered that this region is a site of election for the ray fungus. There is a tendency for the infection to spread from the ileo-cæcal region—(a) to the adjacent peritoneum; (b) to the abdominal wall; (c) to the liver. For this reason it is rare to find the lesion confined to the appendix by the time operation takes place. For this reason, too, the first evidence of cæcal infection may be the involvement of the parietes in the lower right quadrant of the abdomen, in which case there is always a probability that the infection has spread from the bowel. The liver is sometimes involved alone, that is, without obvious intestinal infection. The disease is only to be distinguished from abscess by puncture or by free incision.

3. *The pleura and lung.*—Actinomycosis in these tissues is by no means rare (see section on Respiratory System, pp. 1114, 1163), and the disease should constantly be borne in mind by the practitioner when faced with an obscure case in which indefinite physical signs appear at one base, with cough, fever and (not seldom) hæmoptysis. In some cases a fairly frank pleuritic effusion appears, and the bacteriological examination of the exudate reveals the nature of the disease. In other cases the clinical picture resembles a basal tuberculosis. As the disease progresses the differential diagnosis lies between ray fungus, bronchiectasis and new growth. Hæmoptysis which recurs in the absence of any evidence of tuberculosis in an obscure case of pulmonary disease, is highly suggestive of actinomycosis of the lung. The later stages of the disease still resemble pulmonary tuberculosis: wasting, intermittent fever, purulent expectoration, cough and physical signs of progressive lung infiltration with destruction.

4. *The skin.*—Granulomata sometimes appear in the skin and subcutaneous tissues (a) alone, or (b) complicating the disease in deeper structures.

(a) *The neck and scalp* are the parts most often affected. The initial lesion is a rounded swelling, not very acute, and therefore resembling a tubercle rather than the result of a pyogenic infection, but usually firmer

in texture and larger than the lesion seen in tuberculosis of the skin. It has therefore to be distinguished from sarcoma and from gumma. As the lesion progresses it involves the subcutaneous tissue and tends to ulcerate, after the appearance of one or more soft and dusky-red areas on it. When ulceration occurs at these points, pus escapes, and this contains the tell-tale granules characteristic of the infection. At this stage the appearance is not unlike that of a chronic carbuncle or a suppurating gumma. Ultimately the skin "breaks down" over a considerable area of the swelling, and a chronic ulcer forms, which discharges freely.

(b) Similar skin lesions appear not seldom in association with primary infections of deeper structures, these superficial deposits having the significance of metastatic pyæmic deposits.

5. *The brain*.—The brain, like the skin, may be infected by direct spread from an adjacent lesion, or it may suffer by way of a general pyæmic process. In a case under the observation of C. E. West and one of the writers a chronic otitis media was complicated by granulomata in the scalp, from which the streptothrix was demonstrated in filus and grown in tubes of blood-broth. Cerebral symptoms developed, and the patient died comatose. At the post-mortem examination a large abscess was found in the centrum ovale of one hemisphere, and the mycelial threads were found in the pus in considerable numbers.

Diagnosis.—Hints have been given in the preceding account relative to the differential diagnosis from tuberculoma, sarcoma, pyogenic infection and gumma. *The chief reason why actinomycosis goes unrecognised is that the possibility of its existence is overlooked.* All materials from a suspected case (pus, pleural exudate, sputa, material from liver puncture, excised lymph glands, etc.) should be carefully examined for mycelium, and the bacteriologist should have his attention drawn to the possibility of its presence. Sputa from a case of recurring hæmoptysis, in which a negative report in respect of tubercle bacilli has been returned on several occasions, have been found to contain threads of actinomyces when the necessary investigation has been specially asked for.

Course and Prognosis.—Although these vary much, there is, as may be inferred from remarks already made, a tendency for ray-fungus infection to become pyæmic in character. It is this feature which gives the serious note to prognosis in all cases. In lesions about the jaw and in skin infections that are primary and not associated with visceral infection, the outlook is not nearly so bad as when the lungs, liver or intestinal tract are involved, and when the skin lesions are multiple and secondary. Early diagnosis, if possible before secondary infection (usually staphylococcus) has taken place, adds greatly to the chance of recovery. One of the most important points in connection with prognosis is the uncertainty as to the complete extirpation of the fungus after treatment has been apparently successful. Recurrences are common, and must be allowed for in any thorough programme of treatment.

Treatment.—So soon as the diagnosis is made, the question should be raised whether or not radical surgical measures are practicable. If they are they should be pursued without delay; any abscess or infected area should be drained, or incised and freely curetted; infected lymph glands should be excised; doubtful teeth should be sacrificed. The exhibition of

potassium iodide in full doses should follow these surgical measures, or should take their place in all cases in which they are for some reason impracticable. In some cases it is reasonable to try the patient's response to iodine before planning operative measures. The drug should be given freely diluted with water, and it should be gradually increased from an initial dose of 30 grains in the day to 60 grains, or even to 120 grains if this amount can be tolerated. If recovery takes place the iodine treatment should be renewed for certain periods now and again to guard against relapses.

Vaccine therapy has been attempted in a few cases; the nature of the infecting agent imposes great practical difficulties: if secondary infection by staphylococcus be present inoculation against this microbe should certainly be adopted as a supplementary measure. (See Immune Therapy, p. 42.)

THOMAS HORDER.
JOHN MATTHEWS.

MYCETOMA

Synonyms.—Fungus Foot; Madura Foot.

Definition.—A chronic granulomatous condition affecting the feet, hands, face and sometimes the limbs and internal organs, characterised by swelling of the parts, with the presence of fistulous openings from which an oily, purulent fluid exudes.

Ætiology.—The disease is endemic in different parts of India, but has also been met with in the Sudan, Egypt, Cochin-China, Senegambia, the United States and South America. It is found in country districts, not in towns, and chiefly attacks those who go barefooted. It is thus generally confined to natives, and all ages and both sexes are liable. It is caused by a fungus, the old *Streptothrix madura*. Brumpt has now, however, divided up the mycetomas into 8 different varieties, under different generic names. Some of these are due to species of *Discomyces* (*Nocardia*), others to *Aspergillus* itself or to sub-divisions of it, namely, *Madurella* and *Indiella*. White, red, and black varieties occur clinically.

Pathology.—On section of the affected part the tissues are found to be soft like jelly, and oily. These greyish-yellow, or greyish-red jelly-like masses contain cystic dilatations from which fistulous tracts pass, either into the tissues, or externally, and open through the skin. Both the cysts and sinuses are full of the fungus, which macroscopically appears as white masses like fish's roe, or in other cases as black agglomerations or grains, while in yet another variety the bodies are of a pinkish colour. The bones, fascia, tendons and muscles are ultimately destroyed. Microscopically, the mycelial structure is easily recognised in the white masses.

Symptoms.—The invasion of the fungus takes place through small cuts or abrasions. Once inoculated, the parasites proceed to grow, forming one or several hard nodules in the subcutaneous tissues, usually on the sole of the foot. After several months they ulcerate through the skin and discharge the characteristic contents described above. More nodules then appear in other regions of the affected part, which begins to enlarge permanently, and finally becomes studded with discharging sinuses, out of which an oily, foul-smelling, semi-purulent fluid exudes. There is no special pain, but

if the foot be affected, locomotion is restricted or greatly impeded. Though the foot is the usual site of the lesion, the hand and other parts of the body may also be attacked. The general health remains good at first, but finally anemia and cachexia appear.

Diagnosis.—This can easily be made by finding the characteristic fungus. The differentiation of the different genera and species requires laboratory facilities.

Prognosis.—This is bad, and if the disease be untreated it will finally kill the patient.

Treatment.—The parasite in nature evidently lives on grasses or other plants, therefore walking with bare feet should be avoided. If one or two nodules only be present, these should be freely removed. When the foot is seriously affected it should be amputated, remembering to make the incision well away from any diseased tissue, as otherwise recurrence is sure to take place. Potassium iodide may be tried internally, and should be pushed.

Recently Audrain claims to have cured a case with intravenous injections of mercurochrome (10 c.c. of a 1 per cent. solution) and neo-arsphenamin 0.75 gramme, these being given on alternate weeks—the course consisted of 18 injections of each. There is no definite proof, however, that the case was a genuine one of Mycetoma.

G. CARMICHAEL LOW.

SPOROTRICHOSIS

In this disease, which is much less common than actinomycosis, lesions (granulomata) appear in the skin and rarely in the muscles and bones.

Ætiology.—The causative microbe was first described by Schenk in 1898. Two varieties, *Sporotrichum schenki* and *S. beurmanni*, were originally described, but are now generally regarded as identical. The organisms occur in pus as oval or fusiform spores, and grow in culture as colourless branching septate mycelium, with clusters of brown fusiform spores on the ends of the filaments—occasionally the spores are arranged round the filaments. They stain well with the aniline dyes, but irregularly with Gram's stain. Growth occurs under aerobic conditions only, and on ordinary laboratory media. Cultures are best made from closed lesions, which should be punctured with a wide-bored needle, and the material aspirated should be thickly sown on glucose agar plates, which should be kept at laboratory temperature. The colonies, which appear in from 4 to 10 days, are very characteristic. At first white, thick and leathery, they later become convoluted and coffee-coloured, and still later may become black. Laboratory animals, especially mice and rats, are susceptible, the lesions resembling those in man: but the disease is seldom fatal. The serum of infected individuals agglutinates the spores of the organism, and specific immune bodies can be demonstrated by complement-fixation tests.

Symptoms and Diagnosis.—See p. 1340.

Treatment is on the same lines as described for Actinomycosis.

ASPERGILLOSIS

Infections with aspergillus, usually *A. fumigatus*, have been observed in the middle ear, and on abraded corneæ, as well as in the lung. The organism of the group of Ascomycetes, grows on ordinary laboratory media, and frequently occurs as a contamination.

The cases of lung infection are not very rare (see p. 1115). They resemble cases of chronic pulmonary tuberculosis very closely; indeed, they are generally mistaken for this disease until investigation of the sputa reveals their true character. In most of the cases described there has been a history of previous bronchial or pulmonary disease of a chronic kind; the fungus infection is therefore to be regarded as secondary. The course and the treatment of pulmonary aspergillitis are those of the disease it so closely resembles.

THOMAS HORDER.
JOHN MATTHEWS.

BLASTOMYCOSIS

Definition.—Invasion of the tissues by yeast-like organisms either locally or in a generalised form.

Quite a large number of peculiar pathological conditions have recently been listed, as due to yeast-like bodies or blastomycetes. The parasites multiply in and destroy the tissues, in many instances leading to the death of the host. The fungi implicated have been ascribed to the genera *Saccharomyces*, *Coccidioides*, *Oidium*, *Monilia* and *Cryptococcus*. Warty growths, minute abscess formation and ulceration are the commoner types of lesion observed.

Symptoms.—Clinically the following types have been described. 1. *Cutaneous type*.—This may attack the lips or nose, and may remain local, with no great inclination to spread. 2. *Oral blastomycosis*.—Here the infection attacks the mouth, and spreads gradually to the hard and soft palate, and then to the pharynx, nose and larynx. The lesions, at first verrucous and papillomatous in type, eventually ulcerate, and when extensive cause the death of the patient. 3. *Coccidioidal granuloma*.—As a rule, the lesions of this form appear on the skin surfaces first, or in the subcutaneous tissues, small warty growths appearing with small epidermal or subdermal abscesses, and then the parasites spread to the inner viscera, the infection becoming general. In the affected tissues the parasites can easily be demonstrated. 4. *Gluteal blastomycosis*.—The fully developed condition shows a diffuse brawny thickening of the skin of the buttocks, with sinuses leading into the deeper tissues, some of these communicating with each other and passing deeply inwards. A thin pus exudes from the openings with no grain-like bodies in it, as in actinomycosis. Maxwell's fistulous disease of the buttocks is probably this disease. 5. *Pulmonary blastomycosis*.—Darling has described a series of cases in Panama of a blastomycotic condition of the lung, under the name of histoplasmosis. Post mortem the lungs were studded with nodules like miliary tubercles. These areas contained many yeast-like bodies named by Darling *Histoplasma capsulatum*. The symptoms clinically were anæmia, enlargement of the spleen and fever.

Diagnosis.—This is made by finding the specific organism, and also in some instances by a process of exclusion. The lesions, at the onset, are generally mistaken for tubercle or syphilis, and these conditions must be excluded by clinical and other tests. Oral blastomycosis can easily be mistaken for Espundia or Uta conditions due to *Leishmania americana*. The presence of the *Leishmania* will settle the point.

Prognosis.—This, on the whole, is bad. All the forms are very chronic and little influenced by treatment. The coccidioidal granuloma and pulmonary blastomycosis are always fatal.

Treatment.—Iodide of potassium in large doses is usually recommended. X-rays have been tried, and for local foci of infection, antiseptics of various sorts. Surgical removal, if the lesions are seen early, and strictly limited, may suffice. Small cuts and abrasions should always be attended to, and carefully cleaned, with carbolic or other antiseptic.

HISTOPLASMOSIS

Definition.—A peculiar condition, probably a blastomycosis, found in natives in Panama.

Ætiology.—The parasite named by Darling, its discoverer, *Histoplasma capsulatum*, is now generally supposed to be a yeast akin to a *Cryptococcus*.

Symptoms.—Darling observed the disease in a Chinaman and two negroes in Panama. The malady was associated with an irregular temperature, wasting, anæmia and enlargement of the spleen.

Pathology.—The lungs were studded with small nodules like tubercle. No tubercle bacilli were, however, found, but instead small bodies about half the size of a red blood corpuscle, with what appeared to be a small nucleus. They resembled Leishmanial parasites in some ways, but had no definite kinetonucleus. As already stated, they are now considered to be yeasts, and the disease really to be an internal blastomycosis.

Prognosis.—All the cases seen died.

Treatment.—This would be on the lines of blastomycosis generally. Potassium iodide might be tried.

G. CARMICHAEL LOW.

C. SPIROCHÆTAL INFECTIONS

SPIROCHÆTOSIS ICTERO-HÆMORRHAGICA

This form of jaundice was first differentiated by two Japanese workers, Inada and Ido, in November 1914, who made a full investigation into the ætiology, symptomatology and pathology of the disease. In September 1916, Capt. A. Stokes, R.A.M.C., and Capt. J. A. Ryle, R.A.M.C., published an account of several cases which they carefully investigated amongst our troops in Flanders, and later, in January 1917, they published a further account of their work. Lord Dawson, Lieut.-Col. Hume, R.A.M.C., and Capt. S. P. Bedson, working independently, published in September 1917 a very

complete account of their observations on cases occurring in the army in France. During the past six years this form of jaundice has been closely studied in various parts of the world, and most careful investigations have been made. Thus, in the French army, the disease was found by Martin and Pettit, who published an account of it in October 1916, and have made several further contributions. Investigations on similar lines were made in the Belgian and Italian armies.

Definition.—An acute febrile disease in which jaundice usually appears about the fourth or fifth day, and associated in severe cases with hemorrhages from the nose, lungs, stomach or bowel, or a purpuric rash. It is caused by a specific spirochete.

Ætiology.—*Infection.*—The occurrence of the disease in rats has also been closely studied on the Continent, in Japan, America, etc.; and in March 1918, Dr. A. E. Coles found on examination of rats at Bournemouth that 9 per cent. were infected with the specific spirochete—*Spirochæta* (*Leptospira*) *ictero-hæmorrhagica*. It seems probable that infected rats by means of their infected urine contaminate the soil and water in the locality, and by this means infection is conveyed to man. During the Great War the disease appeared endemic in rat-infested wet trenches. Dogs are susceptible to infection with the spirochete, causing jaundice, and it has been stated that this organism is the common cause of Canine Jaundice. It has not been proved that the disease is conveyed by the consumption of infected food or water, and infection from patient to patient in hospital does not usually occur. Any race may be infected. The disease does not appear to occur in tropical countries, but is associated with temperate climatic conditions and damp.

Pathology.—In three cases described by Dawson, marked evidence of duodenitis and intense inflammation in the area round the ampulla of Vater were found. Stokes did not mention the occurrence of duodenitis in his fatal cases. Both observers describe the bile-duct as being free from inflammatory changes to the naked eye. The liver showed usually few abnormal changes macroscopically, but on microscopical examination some cases showed evidence of cellular degenerative changes. In one case described by Dawson, the liver was diminished in size, its capsule wrinkled, and microscopically there were numerous areas of cell necrosis; in other words, a condition of acute yellow atrophy was found. The condition of acute yellow atrophy in fatal cases of spirochætosus ictero-hæmorrhagica is apparently uncommon, death usually resulting from the toxæmia of the disease rather than from auto-intoxication consequent on acute yellow atrophy. The kidneys showed in all cases some degenerative changes of the epithelial cells. In some, there was evidence of a nephritis which in a certain number was hæmorrhagic in character. In none of Dawson's or Stokes' cases was any enlargement of the spleen found.

The scarcity in number of organisms present in infected patients makes it necessary frequently to resort to guinea-pig experiments in order to discover the spirochete. The guinea-pig is extremely susceptible to the disease, and the introduction of infected material into the intraperitoneal cavity is followed, after an incubation period, by a rapid development of typical symptoms, associated with a heavy infection, so that it is easy to demonstrate the spirochete. In man the blood infection is of short duration, and after the fifth day of the disease, the chances of a positive result diminish.

The infection, as already mentioned, is not a heavy one, so that blood film examinations are usually negative. Introduction of some of the blood (3 c.c.) into a guinea-pig intraperitoneally is likely to give a positive result up to the seventh day of the illness.

The urine, from the tenth day to the fifth week, usually contains spirochaetes, and the centrifugised deposit may yield a positive result on microscopical examination, or a portion injected into a guinea-pig may reproduce the disease in it. The spirochaete obtained from the urine is agglutinated by the blood of the patient after the fourteenth day of the disease. After the fourteenth day of the disease, protective substances conferring immunity are found in the blood, and an immunity test with guinea-pigs was described by the Japanese workers.

Symptoms and Course.—Dawson gives the following account: "The disease has more often a sudden than a gradual onset, and manifests itself by shivering, head and body pains, great prostration, vomiting and diarrhoea. The temperature rises quickly to 102° or higher. During the succeeding 3 or 4 days the conjunctivæ become injected, and herpes, which is liable to become hæmorrhagic, appears on the lips in about 40 per cent. of the patients. Bleeding occurs in most of the severe cases, but uncommonly in the mild cases. It may come from the nose, lungs, stomach, bowel, or as a purpuric rash. Early in the illness a slight hæmoptysis is a valuable diagnostic sign. It is to be noted that hæmorrhage often precedes jaundice in order of appearance.

"The jaundice usually appears on the fourth or fifth day, but may be as early as the second, and as late as the seventh day. It reaches its height about the tenth to twelfth day. In some cases it is intense, and the skin takes the greenish hue met with in complete obstruction of the common bile-duct. Constipation is marked. The stools may become clay-coloured, though in most cases a small quantity of bile gives them a light brown coloration. Tenderness in the upper abdomen is usual. The tongue is furred and brown. The liver is frequently enlarged to the extent of two or three fingers' breadth below the costal margin. The spleen is not palpable. The glands in the axillæ and groins are sometimes enlarged and shotty. In severe cases there are evidences of an acute bronchitis. The respiration rate may rise to 28 or 30, and when a fatal result is impending may resemble that met with in uræmia. The pulse is slow in proportion to the pyrexia, a rate of 75 to 85 being quite usual. In this respect the disease resembles enteric fever, though differing from the latter in that the heart does not block with atropine. The systolic blood pressure is about 120 mm. Hg. being higher than that of enteric fever. The early weakness and prostration are characteristic of the disease. Frontal headache and aching behind the eyeballs are distressing symptoms of the commencement, but diminish as the days pass. The muscular pains last longer, and are at times intense. Twitchings and convulsions may precede or accompany the coma of the fatal cases.

"The urine contains bile in abundance, which may persist for 4 to 5 weeks. Albumin is usually present, and may reach a sixth; casts—hyaline, epithelial and granular—are common. Some French authors lay stress on the evidence of renal insufficiency.

"The course of the illness varies with the severity of the disease. In the acute case an irregular type of pyrexia persists for 10 to 14 days and ends by

lysis. In some instances there is a secondary rise of fever about the beginning of the third week which is difficult to explain, since there is no accompanying exacerbation of symptoms or increase of jaundice. The jaundice will reach its height about the tenth day, and this often coincides with the fall of the temperature. In other cases the temperature will fall earlier while the jaundice is still deepening. Convalescence is slow but recovery is complete."

It is interesting to note that spirochaetosis ictero-haemorrhagica may occur without jaundice. Stokes stated that in 100 cases examined by him, jaundice occurred in only 60 per cent.

Diagnosis.—A comparison of the symptoms of spirochaetosis ictero-haemorrhagica with those of epidemic catarrhal jaundice renders it perfectly clear that the two diseases are quite distinct. In epidemic catarrhal jaundice, the low mortality, the premonitory period of several days before the onset of pyrexia, the absence of herpes and haemorrhagic symptoms, the absence of symptoms of severe toxæmia, and the common occurrence of splenic enlargement are prominent distinguishing features.

Prognosis.—The Japanese workers found a high mortality in their cases—about 30 per cent. Stokes¹ put the mortality figure of his cases as less than 6 per cent. Dawson estimates the mortality as not more than 4 to 5 per cent. in his series.

Treatment.—This is on the lines of epidemic catarrhal jaundice (p. 311). No specific treatment appears to be of value.

W. H. WILLCOX.

RELAPSING FEVER

Synonyms.—Spirochaetosis; Febris Recurrens; Spirillum Fever; Famine Fever; Seven-day Fever.

Definition.—A specific fever, characterised by relapses, due to a spirochaete (spironema) and spread by lice.

Ætiology.—The disease occurs in many parts of the world; it is rare in England, but common in parts of the Continent. In India, Algiers, Cochin-China and in the United States it also occurs freely. All ages are liable and both sexes. The cause of the disease is a spirochaete, and it is customary at the present day to divide the infection into a number of varieties. (1) European relapsing fever, due to the *Treponema recurrentis* (the old spirillum of Obermeier). (2) Asiatic relapsing fever, to *T. carteri*. (3) American relapsing fever, to *T. novyi*. (4) North African relapsing fever, to *T. berberum*. (5) Central African relapsing fever (Tick fever), to *T. duttoni*.

In addition to these human varieties there is a fowl spirochaetosis due to *T. gallinarum*, this disease, as is also African tick fever, being spread by ticks, while the other varieties are all spread by lice.

Pathology.—The treponemata evidently give off toxins, which, acting on the cells of the organs, produce changes similar to those resulting from other toxins. There are no very characteristic appearances met with after death in uncomplicated cases. If this has taken place during the paroxysm, the spleen is enlarged and soft, and the heart muscle, liver and kidneys show cloudy swelling. Infarcts may be found in the kidneys and spleen, and ecchymoses in various parts of the body.

¹ *Lancet*, January 27, 1917.

EUROPEAN FORM.—Symptoms.—The incubation period varies between 2 and 12 days. In accidental inoculations 7 days has been the rule. During this period slight prodromata may occur. The invasion is sudden, with a rigor, and intense pains in the back and limbs. In young persons especially, there may be nausea, vomiting and convulsions. The temperature rises rapidly, reaching 104° F. on the evening of the first day; the pulse is rapid; there may be delirium and sweating; the spleen is enlarged, and, in some epidemics, jaundice is a marked symptom. After the fever has persisted for 5 or 7 days the crisis occurs, the temperature in a few hours falling to normal, accompanied by profuse sweating and diarrhoea. Convalescence is now rapid, and the patient feels well in a few days. In a week, however (the fourteenth day from the commencement of the illness), the temperature rises and the attack is repeated. The second crisis takes place from the twentieth to the twenty-third day, and recovery is again rapid. This usually terminates the illness, but in some instances second or even third relapses are seen.

The parasites are present in the blood during the attacks, but are absent in the apyrexial intervals. Lice become infected by sucking the blood. The treponemata finally appear in the coelomic fluid and nowhere else. During the scratching, which takes place in louse infection, some of the parasites are crushed, and the contents of their coelomic cavities are scattered on the skin, the treponemata entering through the bites of the parasites, e.g. contaminative method of infection (Nicolle, Blaizot, and Conseil).

Complications and Sequelæ.—These are not specially frequent. In some epidemics hæmatemesis and hæmaturia have been noted. Pneumonia may occur. The enlarged spleen has been known to rupture. Ophthalmia and post-febrile paralysis have also been reported. Abortion usually takes place in pregnant women.

Diagnosis.—This is made by finding the specific parasite in the blood. If blood examinations have not been made, the first paroxysm might be missed, but the relapse in 7 days should then reveal the true nature of the trouble.

Prognosis.—Death is not very frequent in the European form, Murchison putting the mortality at 4 per cent. During famines, however, it is much higher, and in some of the varieties in Cochin-China and India it may reach as high as 30 to 40 per cent.

Treatment.—Avoidance of the bites of lice prevents the disease. Salvarsan or neosalvarsan (novarsenobillon) is now generally employed. It may be administered in doses of 0.4 gramme for a man, 0.3 for a woman. As a rule one injection is sufficient, though in some cases a second is required. Apart from this, the disease should be treated by ordinary nursing, diet, etc. Collapse may occur at the crisis and will require stimulants, such as ammonia, strychnine, or digitalis.

ASIATIC RELAPSING FEVER.—This is due to the *T. carteri*. The treponema has been experimentally inoculated into man. Monkeys are also susceptible, but not rats and mice. Clinically the symptoms resemble very closely those of the European form. Rigors are, however, not so common at the commencement, collapse is more frequent at the crisis and the relapses are generally more numerous. Varieties or types have also been described by Carter. (1) A short irregular remitting fever, and (2) the so-called bilious remittent fever or icteric fever of Carter. The parasite is distinguished from *T. recurrentis* and *T. novyi* by immunisation and agglutination tests.

The mortality is high, somewhere about 18 per cent. The treatment is the same as for the European variety.

AMERICAN RELAPSING FEVER.—Due to the *T. novyi*. One relapse is usual in this form. The mortality is low, 2 to 6 per cent.

AFRICAN RELAPSING FEVER.—The fever found in Algiers, Tunis and Egypt is similar to the European, both in its symptoms and method of dissemination, namely, by lice. The form met with in the equatorial regions is different clinically in many ways, and further is transmitted by a bug-like tick, the *Ornithodoros moubata*.

CENTRAL AFRICAN RELAPSING FEVER.—**Synonyms.**—Tick Fever; Tete Disease. This form is found throughout British and Portuguese East Africa, Nyasaland, Uganda and the Congo Free State. The tick becomes infected by sucking the blood of an infected individual, and finally, according to Marchoux and Couvy, transmits the treponemata back to man by the salivary secretion. The ova become infected also, and thus the new generation hereditarily can pass on the disease.

Symptoms.—The period of incubation is usually 7 days. The bite may be accompanied by local inflammatory signs. Prodromata are present, mental heaviness, loss of activity, profuse sweating. The attack comes on gradually with malaise, vomiting and a slight rise of temperature. The temperature then increases, with headache, chilliness and severe pain in the region of the spleen. Vomiting continues, and there may be diarrhoea with streaks of blood. The spleen is enlarged, and scanty treponemata are now found in the blood. Finally, after three or four days, there is a crisis, accompanied by profuse and drenching perspiration. The patient feels weak and tired, but slowly regains his appetite and strength. The disease may end, or there may be an intermission of from 5 to 8 days, after which the first relapse appears. The temperature rises, and the original symptoms reappear. After lasting 3 or 4 days, there is another crisis, and then another period of remission. Second, third and even fourth relapses have been described. When they are prolonged, the patient is greatly weakened and becomes much emaciated.

Complications and Sequelæ.—Iritis is very common.

Diagnosis.—This has to be made from malaria, trypanosomiasis and other febrile conditions. The specific parasite should be demonstrated before diagnosing the condition.

Prognosis.—In Livingstone's time, many natives were reported to have died of the disease. Dutton and Todd also frequently saw fatal cases on the Congo, and the former of these two investigators died of it himself.

Treatment.—The *Ornithodoros* lives in the cracks and crevices of cow-dung houses, and it is therefore dangerous to sleep in such buildings. Destruction of all old mud rest-houses by fire and building of modern ones with cement floors would soon stamp out the disease as far as the European is concerned. The natives seem to have an immunity to the infection. Novarsenobillon injections will cut short the disease and effect a cure. Quinine is of no value.

Somaliland variety.—This form of tick fever is spread by another species of tick, the *O. savignyi*, which lives in the dust of market-places and encampments. It is therefore more difficult to avoid its bite than that of the *O. moubata*, which is bug-like in its habits and only bites by night. The form of the disease is similar to that just described.

BRONCHIAL SPIROCHÆTOSIS

Definition.—A chronic bronchitis associated with spirochætes in the expectoration.

Ætiology.—The condition is common in various parts of the tropics, cases having been reported from Ceylon, the West Indies, the Philippine Islands, West Africa and the Sudan. All races and both sexes are liable.

Castellani discovered the disease in 1905, and named the associated spirochæte the *Spirochæta bronchialis* in 1907. This organism, which is now known as the *Treponema bronchiale*, though resembling the mouth spirochæte, differs from it in several features.

Pathology.—There do not appear to be any records as yet of post-mortem examinations on the condition.

Symptoms.—Castellani describes three types of the disease—an acute, a subacute and a chronic variety.

In the first of these fever, cough, and pains all over the body are present. The expectoration is scanty and muco-purulent. In the second, the attack lasts for several weeks, there is little or no fever, while the expectoration may be pinkish in colour and contain blood. The third variety follows upon an acute or subacute attack, or the onset may be insidious and slow. There is a chronic cough, with scanty often blood-stained expectoration. True hæmoptysis is also seen. Sometimes there is no fever, but in other cases the temperature is hectic. Physical examination reveals a few dry or moist rales, with sometimes some dull areas. The sputum does not show tubercle bacilli, but plenty of spirochætes.

Diagnosis.—This must be made from tubercle and other forms of chronic bronchitis. The repeated absence of tubercle bacilli is important. The spirochætes can be found easily, the precaution of washing out the mouth carefully, always being adopted, to avoid contamination with mouth spirochætes. Paragonimiasis is distinguished by the characteristic ova in the sputum. Animal inoculations should also be performed for further exclusion of tubercle.

Prognosis.—This is good. In chronic cases there may eventually be anemia and wasting.

Treatment.—In the acute cases the patient should be confined to bed and given some mild expectorant. Castellani reports good results from arsenic (Fowler's solution) in the subacute and chronic cases. Salvarsan or some of its derivatives, as novarsenobillon, may also be tried.

RAT-BITE FEVER

Synonyms.—Sodoku; Sokoshio; Rat-bite Disease.

Definition.—A chronic relapsing type of fever, due to a spirillum, the *Spirillum minus* (Carter), transmitted to man by bites of rats infected with the specific germ.

Ætiology.—The disease is common in Japan, and in Bombay, India; cases have also been reported from France, Italy, Spain, America, Britain

(Horder) and East Africa (Low). Any one unfortunate enough to be bitten by an infected rat is liable to acquire the infection.

The spirillum was isolated from rats in Japan, and also by the Japanese in human cases. It is almost certainly the real cause of the disease. At first described as a spirochæte by the Japanese, and known by the name of the *Spirochæta morsus muris*, it has recently been shown by Robertson to be the same as the *Spirillum minor* of Carter, the *Spirochæta muris* of Wenyon, etc., and if one corrects the gender of the specific name, should now read *Spirillum minus*.

Pathology.—The few post-mortem examinations made have not shown any significant changes.

Symptoms.—After being bitten, the wound heals up in an ordinary manner, but in from 2 to 6 weeks pain appears at the site of the old bite, and the scar breaks down. The lymphatics draining the area of the bite then swell and become inflamed, with enlargement of the glands of the area involved; a definite ulcer may now mark the site of the bite, with an angry inflammation spreading away from it, and small vesicles may break out around it. When this has continued for some time, general symptoms make their appearance; the temperature rises to 103° F. or over, there may be rigors, vomiting and nausea, with severe headaches, joint pains, diarrhœa and general malaise. A specific rash then usually appears, dusky coloured, purplish red spots or a coloured patchy erythema over the limbs, trunk and face, which lasts for some time and slowly disappears. After remaining high for 8 days or so, the temperature drops, and the symptoms generally ameliorate. In a varying period of time, however, the first relapse appears, with a return of the symptoms. This in turn disappears, only to be followed by further relapses, which in some of the reported cases have continued for months or even years. Considerable debility follows the attacks, and finally the patient may pass into a very poor state of health. A transient or permanent nephritis may result, and exophthalmos and paresis have been seen in some cases. Ultimately the infection tends slowly to disappear.

Diagnosis.—The history of the rat bite generally gives the clue to the diagnosis. Apart from that, the disease in some ways resembles syphilis, but the Wassermann reaction is negative. The relapsing nature of the disease with the specific skin lesions should clear up any difficulties in coming to a correct interpretation of the complaint.

Prognosis.—With modern treatment this is quite good. Previously it was not so, many cases continuing with chronic symptoms for years. A mortality of 10 per cent. has been given by some authors.

Treatment.—Salvarsan or some of its derivatives should be given, commencing with doses of 0.3 of a gramme. One or two injections are usually sufficient to abolish completely all the symptoms and bring about a permanent cure.

G. CARMICHAEL LOW.

SYPHILIS

. A specific disease due to entry of a micro-organism (*Spirochæta pallida*) into the tissues, either by inoculation into the skin or mucous membrane (acquired syphilis), or by transmission *in utero* (congenital syphilis).

In acquired syphilis a primary sore usually develops at the site of inoculation, and may be followed after a few weeks by a succession of lesions of the skin, mucous membranes, subcutaneous tissues, arteries, muscles, bones, viscera and central nervous system, which recur again and again at varying intervals throughout the patient's life. After many years, degeneration of the parenchyma of the brain (general paresis) or of the spinal cord (tubes dorsalis) may develop. From an early stage changes in the blood serum can be detected by the Wassermann and a variety of flocculation tests. Any or all manifestations, even the primary, may be omitted. In congenital syphilis the systemic disease is the first manifestation.

Ætiology.—The specific micro-organism was discovered by Schaudinn in 1905 and named by him *Treponema pallidum*. Subsequently this was changed to *Spirochaeta pallida*, but the original name still persists in some countries. *Sp. pallida* is a minute organism which in fresh specimens under dark-ground illumination appears as a bluish white, very delicate corkscrew. Its length varies from 5 to 24 μ (average 8 to 10 μ); the distance between individual coils is 1 μ , and the depth of each coil is 1 μ . It is very active in its own ground but slow in moving from place to place. It alternately contracts and expands its coils, bends into loops or forms itself into a right angle. It stains with considerable difficulty, the most usual methods employed being Leishman's or Giemsa's modification of the Romanowsky stain, which dyes it rose-pink, or some method in which silver nitrate is employed, such as Fontana's stain, by which it is stained black. It was first cultivated by Noguchi, who showed it to be an anaerobe. It has been demonstrated in every syphilitic lesion, including the brains of general paralytics, and its ætiological connection with syphilis has been proved experimentally on animals by Metchnikoff and Roux and numerous other workers. It has a life of only a few hours under natural conditions outside the body, and is killed at once by drying and by much feebler antiseptics than suffice to destroy ordinary pathogenic organisms.

The usual methods of transmission are by sexual intercourse and to the fœtus in utero. It does not seem necessary for a person transmitting the disease by intercourse to be suffering at the time from syphilitic lesions of the external genitals. At least, this appears to be the case when men convey the infection, and it is clear that often the semen contains the virus. The period during which a person suffering from syphilis is liable to convey the disease by sexual intercourse varies; after the second year the chances diminish, and it is unusual for infection to be passed on in this manner after the fifth year. There is no doubt, however, that infection can be transmitted to the fœtus by an infected mother up to a much later period, and there is, in fact, no limit to the length of time during which an infected mother may transmit the disease to her unborn child. Accidental infection results from contamination of any minute abrasion with secretion from a syphilitic lesion. The most dangerous from this point of view are the primary sore and the early secondaries. As the age of the infection increases, it becomes more and more difficult to discover *Sp. pallida* in the lesions, and although it is possible to infect an animal with secretion from later or tertiary syphilides, the chances of conveying the disease at this period by ordinary social intercourse are extremely slight. Even in the earlier stages, owing to the low resistance of the organism to external agencies, the risks of accidental infection by

ordinary social intercourse appear to be very slight, judging by the great prevalence of syphilis and yet the very low proportion of extragenital chancres.

Invasion of the tissues.—Although a number of days elapse before a visible lesion appears, within a very few days after infection histological examination of the tissues at the site of inoculation shows that changes are already commencing, and animal experiments have demonstrated that, by this time, the virus has spread throughout the body, infecting particularly the spleen, bone-marrow and testicles. Within the last few years, Kolle and Evers have shown that, after inoculation by scarification, the virus has reached the nearest lymph glands of a rabbit in half an hour, and those of a guinea-pig in 5 minutes.

Pathology.—Although the clinical appearances of syphilitic lesions differ with the age of the infection, the syphilitic lesion of every stage is histologically the same—a granuloma composed of an exudate of plasma cells and lymphocytes around the parasitic focus, with obliterative endarteritis of the vessels. Regarding the exudate as the reaction of the tissues to the toxins evolved by the virus, we may explain the differing clinical appearances which characterise the successive recrudescences of activity of the virus by the increasing sensitiveness of the tissues. Syphilis is characterised by alternate periods of activity and quiescence. In an uncured case the periods of quiescence are probably only apparent, as is shown by the fact that the blood serum gives the Wassermann and other characteristic serum reactions when no other signs of disease are manifest. It has to be remembered, however, that clinical examination does not by any means search all the structures in which the syphilitic organism can produce changes. Doubtless the balance of the struggle between the organism and the tissues rests in most cases with the latter, but the effect of the struggle on them is shown when the spirochaetes temporarily gain the advantage in some spot (usually one where the tissues have been damaged or unduly strained). The response of the tissues is usually the greater the older the infection—i.e. the longer the virus has been acting on them. Thus, if secretion be obtained from—(i.) A primary sore the size of a pin's head; (ii.) a secondary papule when the infection was about 3 months old, and the same size or bigger; and (iii.) a large tertiary lesion, say 10 years old; in the first specimen a large number of syphilitic organisms would be found, in the second only a moderate number, and in the third probably none. Early in the disease, then, a large number of organisms produce only a small lesion, a little later a moderate number produce a moderate lesion, and still later a very small number produce a very large lesion. Histologically, all the lesions are the same; the difference is in their size and their subsequent course.

An important feature of the action of *Sp. pallida* is its effect on blood vessels. The pathology of syphilitic arteritis is discussed on p. 1937. Here it may suffice to sketch the main general effects of syphilis on the vessels. The changes in the vessel wall may lead to aneurysmal dilatation, as in the case of the aorta and other large arteries of the body, and in the cerebral vessels. The aortic valve may be involved in syphilitic mesoarteritis, with resulting regurgitation. Perhaps a more common result of syphilitic arteritis is thrombosis of the vessel, with important effects resulting from failure of the blood to reach the part supplied. Thus, endarteritis obliterans of the coronary arteries leads to myocardial degeneration; and closure of

cerebral and spinal vessels results in paralyses, varying from failure of one cranial nerve nucleus to complete hemiplegia or paraplegia, or death from failure of blood supplies to vital centres. Thrombosis of the vessels implicated in syphilitic lesions has also an important bearing on their clinical progress. Thus, in the case of primary lesions, it may result in failure of anti-syphilitic remedies to reach the parasite in the depths of the lesion, where it may reawaken months after all signs of the disease, even the blood reaction, have disappeared, and give rise to a lesion at the site of the primary sore (*recurrent chancre*). In tertiary lesions the cutting off of nutritional supplies to the centre and the action of the toxin lead to necrosis and liquefaction, but this is never so complete as in tuberculosis. This is seen in the clean-cut ulceration which often characterises tertiary syphilitic granulomata. If bone is involved in the tertiary gumma it may necrose throughout as in the flat bones, or only partially as in the long bones. Where necrosis does not occur, the granulomatous tissue of a syphilitic lesion tends to become more and more fibrous, though at the same time natural forces work towards its removal. There is, so to speak, a race between the two processes. If the amount of exudate is comparatively small, as in some primary and in practically all secondary lesions, the exuded cells may all be removed. If the exudate is a large one, a considerable proportion of it may reach the fibrous stage before the natural scavengers have had time to remove it. Thus many primary lesions are marked by scars of cartilaginous hardness for years afterwards, and gummata, their centres having liquefied, may be enclosed by dense connective tissue. Bone gummata, in fact, are often ringed by heaped up bone of ivory hardness.

Scarring from formation of fibrous tissue and its subsequent contraction may have important effects on viscera. For example, an active tertiary hepatitis may be stopped by suitable treatment, but the subsequent contraction of the scars may cripple the organ hopelessly. Similarly, the aortic valve cusps may be rendered permanently incompetent by the scarring following on stoppage of the syphilitic process.

The changes which occur when the parenchyma of the central nervous system is invaded are described elsewhere.

Incubation and early course.—The incubation period varies from a minimum of about 10 days to a maximum of about 90, with an average of 4 to 5 weeks. A small papule then appears at the site of inoculation, and quickly enlarges to a round or oval sore about the size of a threepenny bit; the centre usually becomes eroded, or perhaps more deeply ulcerated, and the broken surface is surrounded by a dull-red areola varying in width from half to 2 or 3 mm. Beyond the confines of the eroded area the tissues are infiltrated, feeling definitely tougher to the palpating finger than do the corresponding tissues on the other side of the part. With age this induration becomes more and more pronounced until, in the case of some primary sores, it feels as if there were a button embedded in the tissues. The sore does not bleed easily when scraped, but serum oozes freely from it, and this serum usually teems with syphilitic organisms. The sore is comparatively painless.

These are the main characteristics of all primary syphilitic sores, but individual features vary with the site. Thus the most indurated are those on the under-surface and mouth of the prepuce. In the case of a sore at the

reflection of the prepuce on to the *corona glandis*, when the prepuce is retracted, the lesion flicks over like a plate turning on its edge. A sore at the mouth of the prepuce often converts it to a fibrous ring. Induration is easy to elicit in sores affecting one wall of the *fossa navicularis*, which then feels as if a plate were embedded in it. In primary sores of the glans itself, induration is difficult to elicit owing to tightness of the tissues, but the sore is easy to recognise by its dull-red areola, even contour, eroded centre, and indolent progress. Primary sores of the skin are dark red, covered with a dark scab, and tough in consistency. Ulceration is usually more marked in sores affecting the mouth and under-surface of the prepuce, the skin at the penoscrotal angle, the tissues around the nails, the lips and the tonsils. Almost all primary sores are comparatively painless, but when affecting the terminal phalanx of a finger or thumb they may be exquisitely painful; this, no doubt, partly accounts for the fact that primary sores in this situation are so often diagnosed as 'whitlow'. The primary sore affecting the prepuce, the skin of the penis, or (especially) the female labia may be accompanied by a toughly indurated oedema of the affected parts, which become somewhat livid.

The course of the primary sore varies greatly. In some cases the lesion is fleeting and apt to pass unnoticed. Such a sore is by no means an unmixed blessing, since its apparent triviality may lead to neglect of treatment, with the possible result that years later tabes or general paresis supervenes. The history of a substantial proportion of cases of tabes and general paresis is that the initial lesion was either unnoticed or was very trivial. It is possible that this may be due to the fact that the infecting organism is a spirochæte with no great capacity for causing lesions of the surface structures, but with a predilection for the parenchyma of the nervous system (neurotropic virus). On the other hand, the triviality of the sore may have led more certainly to the graver late manifestations because of neglect of treatment. The ordinary sore which remains untreated lasts for a month or longer, and long after the erosion has healed over, a button of indurated tissue may remain to mark the site. Syphilitic organisms have been found by histological examination of such scars many years later. Weeks or months after it has healed the sore may break down again, the resulting lesion approaching then more closely to the characters of a tertiary ulcer. It is probable that in these cases the syphilitic organism buried in the depths of the scar has gradually reawakened to activity. When a sore becomes infected by secondary organisms, ulceration is a more prominent feature, and in rare instances the ulceration is phagedenic. In such cases the surrounding tissues very rapidly become black and necrotic, and the resulting loss of tissue may involve large portions of the external genitals.

Shortly after the appearance of the primary sore the nearest lymph glands often become painlessly enlarged, and in the case of the penis the lymphatics running from the sore can frequently be felt below the skin. The affected glands may reach a large size, bulging out the overlying skin; and this, with the fact that there is no reddening of the skin or other sign of acute inflammation, often gives the clue to the nature of the sore on which it depends. Syphilitic buboes do not usually suppurate, but may do so if the sore has become contaminated by secondary organisms, so that supuration should not weigh heavily against a diagnosis of syphilis. A week or so after the local lymph glands have begun to enlarge there is universal

adenitis, which can be appreciated by palpation, particularly of the epitrochlear, axillary and cervical glands. About this time, or when the sore is about 15 days old, the blood serum often for the first time gives positive Wassermann and other serum reactions, such as the Meinicke, Sachs-Georgi, Kahn, and Sigma of Dreyer and Ward. The last three depend on the flocculation which occurs after incubation for some hours of heated and diluted syphilitic serum with diluted extract of heart muscle prepared by special methods. The three flocculation tests mentioned here are, on the whole, more delicate with serum than is the Wassermann, but present indications are that the Sachs-Georgi and Sigma are less delicate with cerebro-spinal fluid. The percentage of cases in which the Wassermann and flocculation reactions are given increases with the age of the disease until the outbreak of the skin lesions which manifest the next or secondary stage. Practically 100 per cent. of patients in the secondary stage are positive.

Diagnosis of the Primary Stage.—The guiding characteristics by which primary syphilitic sores are distinguished from others are the incubation period, colour, indolence, surrounding infiltration, comparative painlessness, slighter tendency to bleed, indolent enlargement of neighbouring glands, and the presence of *Sp. pallida* in the serum exudate from the sore. The length of the incubation period is a guide only when the patient has not been exposed to infection for over 10 days.

Of sores which may appear on the genitals, herpetic lesions are multiple and fairly closely set, so that when the tops of the minute blisters have been rubbed off, a composite lesion is seen made up of a number of minute circles or of arcs of circles. Herpes is not accompanied by induration or enlargement of neighbouring glands, and is usually attended by some degree of irritation.

Chancroid has an incubation period of only a few days; the sore is of a more inflammatory nature, being undermined and more definitely ulcerated, rather than eroded; excavated, rather than worn down. The edge is much more irregular and is merely tipped with red, which is of a much brighter shade than the areola surrounding a primary syphilitic sore. A case should never be dismissed at once as chancroid, since there may be a double infection, and syphilis be incubating in the sore; unless a close watch is kept, the thickening and induration which develop later in a mixed chancre may pass unnoticed, and the physician receive a rude shock from the outbreak of a syphilitic eruption in a case which he has diagnosed as chancroid. A good rule is to continue microscopical examination at intervals until the sore heals and to test the blood for the serum reactions for 3 months. Chancroid may be accompanied by a bubo which tends to suppurate. A syphilitic bubo may, however, suppurate, so that it would be a mistake to exclude syphilis on the sole ground of suppuration. If the glands, though distinctly enlarged, showed no signs of active inflammation, it would be strong evidence in favour of syphilis.

Scabietic runs on the glans and skin of the penis are often diagnosed as syphilis. They are mound-like, not eroded, have no areola, are not indurated, and, of course, the serum exudate contains no syphilitic organisms.

Syphilitic sores in parts of the body other than the genitals are often overlooked, mainly because syphilis is not thought of in those parts. A unilateral tonsillitis should arouse suspicion, especially if associated with

painless enlargement of the submaxillary glands on one side. Similarly, the effie to the nature of a lip chancre may be given by the glands. Primary sores affecting the terminal phalanx of a thumb or finger are often extremely painful and simulate whitlows rather closely. The syphilitic sore is more brawny, and remains so considerably longer after the sore has been lanced.

In any case of doubt a specimen of serum should be taken from the sore and examined microscopically. This should be done before any antiseptics have been applied, as they kill off the organisms in the superficial layers and prejudice the success of the examination. To obtain a specimen which has to be sent away to a laboratory for examination, the sore should first be cleaned with a swab of lint and a fairly deep puncture made in its margin with the point of a scalpel or a vaccination lancet. The sore should then be squeezed and the specimen collected after the serum has oozed for a few minutes. The serum should be allowed to run into a capillary tube, only one end of which should be sealed. Alternatively a good method is to puncture the nearest enlarged gland and aspirate a little of the gland juice. A moderately stout needle is run obliquely into the gland, and a few minims of sterile saline injected into it. The gland is massaged and aspiration applied by a syringe. The fluid aspirated is forced into a watch-glass and collected in a capillary tube as above. It is always a good plan to send two or three specimens, as it often happens that the first specimen is negative, while the second or third taken some minutes later, when the serum has had an opportunity of oozing up from the deeper layers, is positive. Also it is good to remember that, just as a clinician would search longer a microscopical specimen from a sore which he believed to be syphilitic, so would the pathologist at a distance if he were told that the sore was strongly suspicious. The information cannot conjure the syphilitic organism into the microscopical field. When the necessary apparatus is at hand it is always better to examine the specimen at once by dark-ground illumination.

Spiral organisms other than *Sp. pallida* may be seen in a specimen obtained from the genitals or the mouth. They are largely eliminated by taking care to clean the surface of the lesion before collecting the specimen, but some may still be included. All coarsely spiral organisms which appear thick should be excluded at once. To the observer who has once observed *Sp. pallida* closely, only three others will cause difficulty:

A fairly fine spirochæte, with closely set spirals, often found in specimens from the genitals; it is about twice as thick as *Sp. pallida*, shines more brightly, has a slightly rusty tinge, and spirals which are by no means so cleanly cut as those of *Sp. pallida*. Two very fine spirochætes, found in the mouth, and both as fine as, or finer than, *Sp. pallida*. One is distinguished by the angularity of its turns, the other by its spirals being much more closely set, so that it looks like a piece of twisted silk.

Secondary Stage.—Usually, but by no means always, a generalised rash appears three or four weeks after the sore. The eruption generally starts on the sides of the trunk in the form of pinkish spots, varying in size from a split-pea to a little-finger nail, which deepen in colour with age to a dull-red or somewhat brownish tint. At first they may be difficult to see, requiring a good light, but become more manifest after the patient has stood stripped for a few minutes. The eruption spreads gradually over the trunk

and limbs, and fades in a few weeks, leaving little or no staining. It may recur at a later period, and the spots are then annular or ring-like.

After the fading of the first roseola, a peculiar change in the distribution of the pigment may occur, especially on the necks of brunettes. The neck becomes generally discoloured, or, more commonly, assumes a dappled appearance (syphilitic leucodermia), as if the pigment had been washed out of a number of circular areas, each about the size of the end of a finger-tip, and had collected at the margins.

The *papular* eruption follows closely on the heels of the roseolar, and takes a number of different forms. The commonest, and generally the earliest, consists of numbers of dome-shaped, dull-red, indurated papules distributed generally over the trunk, limbs and face. Most of them are about the size of a lentil, but scattered among the smaller papules may be a considerable number of others which are larger, sometimes reaching the size of a three-penny-bit. The individual papule feels indiarubbery, and when it is squeezed between finger and thumb appears glistening white, while its surface epithelium cracks slightly. Variations of the ordinary papular eruption are the papulo-squamous, squamous, papulo-pustular and pustular. In the *papulo-squamous* a large proportion of the papules are covered at their centres by loose scales. The *squamous* syphilide is a papular eruption in which scaling is a still more prominent feature. In the *papulo-pustular* syphilide the centre of the papule necroses, and the appearance is rather that of a suppurating acne spot. An extension of this is the form in which the whole papule breaks down, and the *pustular* syphilide results. When extensive, the pustular syphilide may resemble a varicellar or a variolous eruption. A more severe and malignant form is the *ecthymatous* type, in which the papule breaks down quickly, and the underlying tissues are eroded or ulcerated. As the destruction of tissue extends, the secretion dries to a crust. This may become heaped up by the deposit of successive layers, and the result is a *blackish crust, shaped like a limpet (rupia)*.

Peculiar appearances of the papular syphilide in different situations.—Between the buttocks, on the lateral surfaces of the scrotum, and on the labia, the papular syphilide often becomes very prominent and wart-like, with a greyish-white appearance; these syphilides are called *broad condylomata*. The whole of the contiguous surfaces of the buttocks may be covered with these lesions, which may diffuse into a large, moist, wart-like plaque with a few outlying growths. On the front and back of the scrotum the papular syphilide often takes the form of glistening-white, slightly raised rings with brownish centres. These are best displayed by stretching out the scrotal skin as if it were a piece of cloth under examination. Between the toes, under the pendant mammae, and in almost all moist situations, papules tend to run together and, their sodden covering often becoming rubbed off, a moist, pinkish-red surface, fringed with loosened epithelium, is left. Condylomata and moist papules generally exude serum freely; the parts appear unnaturally moist, and the secretion is rich in *Sp. pallida*. On the palms and soles the papules appear as flat or slightly raised spots, varying in size from a split-pea to a sixpence. They scale easily, leaving a collar of loosened epithelium surrounding the shining papule, which feels almost corn-like. Sometimes the lesions run together into large plaques traversed by weeping fissures. The finger-nails may show characteristic

changes, more especially in the recurrent secondary stages. The end of the finger becomes pinkish-red and bulbous, and the reflection of the skin on the nail is occupied by weeping granulations. The nail becomes brittle and lustreless and is shed. The papular syphilide may be well marked on the forehead, following the margin of the hair (*corona veneris*), and it is often possible to find many papules in the hairy scalp. On other parts of the face, especially about the naso-labial fold and the chin, the papules are often set in rings. In some cases the facial lesions may be prominent, especially at a naso-labial junction, appearing as moist, fungating growths like condylomata. On account of its similarity to yaws this syphilide is called *fram-bœsiform*. When the papular eruption of the type under discussion recurs on the body it tends to be distributed in rings, as in the case of other types of recurrent syphilide.

The *follicular* or conical type of papular syphilide usually occurs at a later period than the dome-shaped variety just described. There are two main types, the small and the large follicular. The *small* follicular syphilide occurs in small clusters of minute, pin-head, brownish papules affecting the hair-follicles and often thickly distributed on the back. The affected areas, each about 1 cm. across, have a *goose-skin* appearance, and the part generally looks as if it had not been properly washed. The *large* follicular syphilide is usually disposed in circles the size of half a crown or larger, the centre of the circle being occupied by a particularly large papule, round which a ring of smaller satellites is ranged; this is the *corymbose* syphilide. It usually appears comparatively late, say about the end of a year or eighteen months, and its characters approach closely to those of the nodular cutaneous syphilide, to be discussed under tertiary lesions.

The syphilitic eruption in the mouth.--Before the rash appears on the body the soft palate may become erythematous, contrasting with the pallid hard palate. Other lesions of the mouth usually make their first appearance at the time of the papular syphilide of the skin. On the mucous surface of the lips and the pillars of the fauces the early syphilide is a *greyish-white* patch, edged with a *pinkish-red* areola, which marks it off from the surrounding mucous surface. On the pillars of the fauces the appearance is that of a *snail-track* creeping up over the pillar on to the soft palate. On the tonsil the lesion tends to ulcerate rather deeply. The mucous patch on the lip is usually round or oval and, if it crosses the angle of the mouth, is fissured. On the sides of the tongue fissuring and ulceration are more pronounced, but on the under-surface the lesion may be condylomatous in type, while on the dorsum the commonest lesions are pink, bald spots, the pile of the tongue having been rubbed off each papule. The secretion from these lesions teems with syphilitic organisms, and is very contagious.

The *hair* is shed to a varying degree in the secondary stage. In most cases there is some thinning, which is not particularly noticeable; in others it falls in a patchy manner, giving the back of the head a moth-eaten appearance; and in a few the patient may become temporarily bald. The beard and eyebrows may participate in these changes.

Joints and bursæ are not often affected in secondary syphilis, but occasionally an *acute synovitis* occurs. It is fairly painful, and usually worse at night. A more indolent form of synovitis causes swelling without pain or great limitation of movement. The tendon-sheaths may be affected

similarly, and the tendency to formation of adhesions may lead to permanent limitation of movement. Mild *periostitis* may occur in the secondary stage, but bone-affections are commoner in the tertiary.

From about the sixth month, or even earlier, the patient may develop symptoms pointing to syphilitic disease of the central nervous system, which are dealt with elsewhere. It is well to remember that in over 30 per cent. of cases in the secondary stage changes in the cerebro-spinal fluid indicate invasion of the central nervous system, though only a very small proportion of these cases show clinical signs of nervous disease.

Constitutional symptoms—Fever.—Even in the incubation period rigor followed by some degree of fever and pains in the limbs may occur. In some cases, towards the end of the primary stage, or on the outbreak of the rash, the patient's temperature may become irregular, the pyrexia being intermittent, continuous or remittent, and accompanied by some constitutional disturbance. Sometimes just before the outbreak of the eruption, and during the early part of the secondary stage, there is a feeling of aching in all the limbs, as if the patient had been taking too much exercise. In some cases at this time there may be definite lightning pains, which lends support to the idea that all these symptoms may possibly be due to meningeal involvement and irritation. In the early secondary stage also, headache may be severe, and may not improbably be due also to meningeal involvement.

Anæmia.—The organism of syphilis affects particularly the hæmopoietic organs, and it is not surprising that untreated syphilis is usually accompanied by some degree of anæmia. The anæmia is usually of the secondary type, with reduction of the red blood corpuscles to an average between 4,000,000 and 5,000,000 per c.mm. The loss is more particularly displayed in the hæmoglobin content, which is usually reduced, so that the colour index may be as low as 70 per cent. of the normal. The early stage is accompanied by a moderate leucocytosis which may reach a cell-count of 20,000 per c.mm. The increase of leucocytes is made up chiefly of lymphocytes, which is to be expected in view of the fact that the organism of syphilis stimulates a local exudate of lymphocytes and plasma-cells, of which the infiltration is largely composed. In rare cases the anæmia may be much more severe, Müller having reported one with a blood state resembling that found in pernicious anæmia. Justus, in 1895, introduced a new test based on the reduction of the hæmoglobin content which followed the first administration of mercury in a case of syphilis, but this is now of only academic interest.

Diagnosis of Secondary Eruptions.—The maculo-roseolar syphilide is fairly easy to distinguish by the history of a primary sore with indolent adenitis; by the subcuticular, deeply grounded appearance of the spots, which first appear on the flanks, very rarely itch, and are of a pinkish or dull-red rather than a bright-red tinge, and by the coincidence of positive serum reactions. Other erythematata are brighter red, more irritable, and often affect the backs of the hands. *Seborrhæa* is more superficial, not well grounded in the skin, and is more scaly, the scales being greasy. *Pityriasis rosea* is often mistaken for syphilis, but the lesions are brighter in colour and more irritable; they tend to become annular, with their centres covered by branny scales. *Ringworm* is more superficial and irritable, and the fungus can be found in scrapings from its border. *Tinea cruris* or *dhobie's itch*

affects a triangle at the upper and inner part of the thigh ; it is brighter red, more irritable, and quite superficial. *Drug rashes* are more inflammatory and irritable ; they appear more suddenly, and are associated with a history of the patient having taken such a drug as copaiba, cubebs, antipyrine, quinine or belladonna. The *eruptions of specific fevers* are usually accompanied by more pronounced constitutional symptoms.

The ordinary dome-shaped papular syphilide is usually easy to distinguish from a non-syphilitic eruption. The indurated feel of the papule, its shining appearance when pinched, its readiness to scale, and its dull or pinkish-red colour are valuable diagnostic signs, as is also the association with mouth and throat lesions. The different appearances which a papular syphilide presents in different parts of the body, such as dry papules on the trunk and most areas of the limbs, moist papules on the scrotum, between the toes and in other moist, warm parts, and wart-like condylomata on the scrotum, contrast strongly with non-syphilitic dermatoses which are true to type wherever situated. The microscopic test should always be applied in any doubtful case, and very rarely fails, even with the papulo-pustular or the pustular syphilide. *Acne spots* are more inflammatory, and tend also to affect the upper front of the chest and between the shoulders behind, rather than the flanks, loins and limbs. Pus can usually be expressed from blind acne pimples when they are pricked and squeezed. *Molluscum* spots are white and umbilicated, while caseous matter can be squeezed from their centres. *Lichen ruber planus* is characterised by flatter, smaller, polygonal spots of a violet tinge and waxy covering ; it is more irritable. *Psoriasis* is usually less indurated, more superficial, bleeds at a number of points when slightly scraped, and affects the extensor rather than the flexor surfaces of the limbs ; the scales are more silvery, and in moist situations the rash remains true to type, contrasting with the syphilide, which here becomes sodden with the secretion that freely oozes from it. *Varicellar spots* are more superficial and not associated with mouth and throat lesions. *Variola* is quicker in development and change, and tends to affect the backs of the hands and wrists. *Bromide and iodide* eruptions appear more suddenly, and are considerably more irritable. The deeper forms of pustular syphilide with considerable crusting, such as the superficial and deep ecthymatous, or the rupial, are distinguished from ordinary *impetigo* by the darker colour of the crusts, the circular rather than linear shape of the lesions, and the greater degree of tissue destruction below the crusts. *Scabies* is often mistaken for a crusted syphilide, and vice versa. The individual scabietic lesion is easy to recognise, but the tendency is to forget that scabies and syphilis often coexist.

Secondary syphilitic mouth lesions are easily diagnosed by the characters mentioned. *Vincent's angina* may cause confusion, but there is no pinkish areola, and the microscope easily settles the diagnosis.

Tertiary Lesions.—There is no sharply dividing line between the secondary stage and the tertiary, since the earliest tertiary lesion, the nodular cutaneous, is merely a collection of papules, which are more deeply embedded, and tend more to ulceration than the papules of what is called the early secondary stage.

The *nodular cutaneous syphilide* occurs in one or more isolated areas of the skin as a collection of skin gummata, each about the size of a pea, often running into one another to form a more or less continuous, brownish-red

ridge, which describes a circle, or may be made up of the arcs of a number of circles so as to produce a snake-like line of varying length. Sometimes the affected area looks as if a number of groups of concentric circles had been described on the skin; sometimes two or three very short concentric arcs are seen. The affected area may be as small as a finger-nail or larger than a hand. The individual gummata may degenerate only so slightly as to produce some scaling, or may ulcerate more deeply and become crusted. The lesion extends centrifugally, and leaves in its wake a reddish-stained area, which shows little evidence of scarring; or a supple, papery scar which shows well the concentric distribution of the lesion. Sometimes the nodules do not resolve as the lesion extends, and a red nodular plaque of indurated tissue is formed. On the palms the lesion may form the characteristic serpiginous pattern described above, or affect chiefly the folds, which become fissured. In some ulcerative cases extension is more rapid than healing, and a large patch of small skin ulcers may be left in the wake of the advancing arcs of new lesions. Very rarely, and then mostly when situated close to the angles of the mouth, or at a nasal orifice, the ulcer may become phagedenic, causing most extensive destruction of tissue. The areas of the body which are more commonly affected are the calves, about the iliac crests, over the shoulder-blades, the palms of the hands, the flexor surfaces of the joints, and the nose, forehead and mouth region. The areas chiefly affected are those exposed to injury or constant friction, and an odd distribution can usually be traced to the patient's occupation, exposing the part to much stress or injury. A similar type of lesion may affect the soft palate and lead to considerable ulceration and deformity.

Gummata of the tissues underlying the skin are usually, though by no means invariably, later than skin gummata. Those of the subcutaneous tissues and muscles grow up as indiarubbery lumps which vary in size from a shrapnel bullet to an orange, or larger. They are painless, quietly expanding growths, which tend to break down in the centre and, opening through the skin, discharge their contents, leaving clean-cut ulcers with overhanging edges, tough, wash-leather sloughs occupying the bases. Sometimes, instead of a discrete gumma forming in the affected muscles, these are diffusely infiltrated, and much deformity results when the degenerated tissue is replaced by scar.

The *joints, bursæ, and tendon-sheaths* are not often invaded in tertiary syphilis. When they are, the parts affected are, again, those most exposed to stress and strain, such as the knee-joint and the prepatellar bursa. The swelling is easy to recognise by its soft, indiarubber-like consistence; as also by the fact that it follows the lines of the joint, bursa or tendon-sheath affected, and by the absence of signs of active inflammation.

The *bones* are affected in tertiary syphilis in different ways. In the long bones the most usual manifestation in acquired syphilis is a localised gumma, which eventually necroses in the centre, while the edge becomes converted to a raised circle of ivory hard bone. The process is accompanied by boring or gnawing pain, which is particularly severe at night. The contents are discharged through the skin, leaving an intractable ulcer, at the bottom of which bare bone may be felt. If the process begins deeper, the local swelling may not be so obvious and, eventually, with discharge of the necrotic contents, one or two fistulous openings lead to the interior of the bone. Diffuse osteitis

and periostitis are not so common in acquired as in congenital syphilis. A sign of congenital syphilis in adolescents and adults is the sabre-scarbared tibia resulting from diffuse periostitis in earlier years; the bone is thickened from before backwards, and its anterior crest is curved with its convexity forwards, giving the bone the shape from which the condition derives its name. Of the long bones, the most commonly affected in acquired syphilis are the clavicle (sterno-clavicular joint), sternum, ribs, tibia and femur; but no bone is immune, and the process is particularly apt to affect those which have received a blow or other injury. Syphilitic dactylitis is very uncommon. Usually the proximal phalanx is affected, and a quiet, painless swelling results. Sometimes a sinus forms and the bone becomes rarefied. In other cases the whole bone becomes permanently thickened, and in still others absorption of the product may result in permanent shortening of the phalanx. The flat bones of the skull tend especially to undergo caries as a result of gummatous infiltration, and some of the worst mutilations which result from syphilis, and make it so dreaded, are those resulting from caries of the bones entering into the formation of the nose and palate. Here, after a period during which the patient is afflicted by ozæna, the bridge of the nose may fall in, or a large perforation of the hard palate suddenly make its appearance. In others the process may spread to the skin, and the most disfiguring ulceration of the face ensue. Gummata of the frontal and parietal bones may start in the inner or the outer table. In the latter case a swelling is followed by breaking down of the centre. Under the influence of treatment this may gradually be absorbed; otherwise a circular or perhaps a horseshoe- or trefoil-shaped ulcer, rimmed with an ivory-hard ridge, results. The ulcer may perforate the skull, but the general cavity of the cranium has usually by then become shut off from the affected area. When the gumma starts in the inner table, irritative and pressure symptoms may mark its first appearance. Gummata of the vertebræ are uncommon; according to their situation they may lead to retro-pharyngeal, lumbar or iliac abscess. Rarely they may involve the spinal canal and cause symptoms of pressure on the cord.

Tertiary syphilis of the *testicle* occurs in two forms, which are often combined, the diffuse interstitial and the nodular. In the former the testicle slowly enlarges, becomes heavy, but remains quite smooth, and the testicular sensation is lost. The nodular form, often engrafted on the diffuse, is characterised by the formation of gummata which may project like bosses from the surface of the testis. The epididymis is usually not palpable, and commonly the cord is moderately thickened. The condition may be accompanied by a hydrocele. Usually, in the end, the testicle shrinks, but the gummata may break down, giving rise to a form of *fungus testis*.

The *mouth and throat* often suffer severely in tertiary syphilis. Gumma of the tonsil is followed by severe ulceration. The soft palate may be strewn with a number of pea-like nodules which often ulcerate and result in all grades of deformity. Perforation, usually at the junction with the hard palate, is common, and sometimes the soft palate becomes adherent to the posterior pharyngeal wall. Perforation of the hard palate may result from gummata commencing on the mouth side.

The *tongue* may be the seat of discrete gummata which eventually reach the surface and cause deeply punched-out ulcers. A form analogous to the

nodular cutaneous syphilide consists of a number of pea-like nodules affecting a moderately large area of the tongue. This becomes swollen and very tender, but, unlike the diffuse glossitis mentioned below, is very amenable to treatment. A much commoner manifestation of tertiary syphilis of the tongue is diffuse glossitis, which may be deep or superficial. The affected portions are swollen and the surface is smooth, hard, inelastic and usually covered by a bluish-white pellicle (*leucoplakia*). On retrogression, the tongue becomes cut up into numerous islands by fissures of varying depth. The tongue is tender, and intolerant of spices and hot food.

The insides of the cheeks, along a line from the angle of the mouth opposite the gap between the upper and lower teeth, are often affected with leucoplakia. The area forms a bluish-white ridge cut up herring-bone fashion, which is quite characteristic. It may be the only clinical sign of syphilis which the patient may show.

In the tertiary stage, fever has been noted in a number of cases, and its dependence on syphilis has been shown by its response to anti-syphilitic treatment. The fever may simulate almost every type, and may be long-continued. It has been noted more particularly in connection with syphilis of the liver. It may be mistaken for rheumatic fever in cases where there is some arthritic pain due to periostitis in the vicinity of joints; for typhoid fever and for tuberculosis. These examples may serve to show the type of fever and its long continuance in some cases, and point to the necessity of an investigation with syphilis in view in cases of obscure pyrexia.

Diagnosis of Tertiary Lesions.—An indolent swelling, or an ulcer preceded by a swelling, the lesion being obviously deeply embedded in the tissues or breaking down in the middle (which contains a characteristically gummy material) and sclerosing at the margin, with a circular, crescentic or evenly sinuous contour, and brownish-red in colour, should always arouse a suspicion of syphilis. Denial of primary sore, or of secondary lesions, is of no importance, as they may long ago have been forgotten. The positive serum reactions may mislead, since by no means all ulcers in an old syphilitic are themselves syphilitic. On the other hand, negative serum reactions are rather strong evidence against tertiary syphilis. *Epithelioma* is perhaps more likely to be confused with tertiary syphilis when the lesion is in the mouth, but epithelioma has a considerably harder margin, and the edge is rolled, not clean-cut. A positive serum reaction may prove to be a trap, as epithelioma is often engrafted on an old syphilitic glossitis. Ulcers on the legs resulting from *varicose veins* or *impetigo* may arouse a suspicion of syphilis. They are usually much less regular in contour and associated with more inflammatory manifestations. Syphilitic orchitis is easily distinguished from other conditions by the evenly smooth hardness of the testicle, the weight and the absence of testicular feeling.

CONGENITAL SYPHILIS

An infected mother can transmit syphilis to her offspring long after she has ceased to be sexually contagious. Syphilis transmitted to the fœtus during the early months or years of the mother's disease is usually fatal, and a miscarriage results. In successive pregnancies the virulence of the disease seems to become more and more mitigated, so that infants born dead

at term are succeeded by those dying shortly afterwards, by those surviving though diseased, and eventually by healthy children. The family history does not always pursue this regular course of gradual attenuation, however, since in some families an apparently healthy child may be preceded and succeeded by some miscarriages, or stillborn children. It has even happened in the case of twins that one is healthy and the other diseased.

Symptoms.—A syphilitic infant born alive may show an eruption of bullæ or pustules resting on dark-red bases. The secretion contains the organism of syphilis in large numbers. A commoner event is the maculo-roseolar eruption, coming on about 3 weeks or a month after birth. It selects chiefly the napkin area, the neighbourhood of the nose and mouth, and the palms and soles, but the whole trunk and limbs may be affected. The macules often run together into large patches which may be annular, as in the recurrent form of acquired syphilis. In moist areas, and where the rash is exposed to friction, the surrounding surface secretes serum freely and becomes red and glazed, or crusted. Condylomata and moist papules occur and ulcerative fissures or *rhagades* may form at the angles of the mouth. These often leave radiating scars which remain as stigmata of the disease. Syphilitic infants may retain a fairly well-nourished appearance, but often become emaciated, with yellowish, papery skin and a wizened, old-man appearance. Simultaneously with the skin eruptions, the nails may become opaque and irregular. In others there is infiltration and oozing of serum around the nail, which is loosened and shed. The hair is often shed extensively; on the other hand, syphilitic infants may grow an abundant crop of hair, which has been called the "syphilitic mop," though it occurs in other diseases. Mucous patches appear in the mouth and throat, and involvement of the mouth and larynx is marked by the well-known "snuffles" and the hoarse, raucous cry of the syphilitic infant. Suppurative otitis media is often an early manifestation, and leads to hopeless deafness.

Tertiary lesions may appear very early, or not until the ages of 7, 14, 21, or even later. Thus diffuse interstitial orchitis may occur during the first 6 months. Skin gummata may appear in the first year or two as small infiltrates which break in the centre to discharge their mucoid contents. Tertiary lesions of the mouth and throat may show themselves at any time after the first year, and result in perforation of the palate and considerable deformity of the soft palate and faucial pillars. Destruction of the nasal support results in saddle-nose, and from the age of about 11 there is a liability to sudden deafness from gummatous changes of the internal ear. The affection usually starts in one ear, but quickly follows in the other, and the child becomes permanently deaf. Choroiditis and iritis may appear as early as the age of 5 months, and, unless properly treated, lead to blindness, or considerable impairment of sight. Interstitial keratitis may begin at the age of 6 or not until the patient is between 20 and 30. Usually it starts in one eye, and the other follows suit in a few months, often in spite of treatment. The cornea of the affected eye gradually becomes opaque from the margin inwards, and this is followed by vascularisation, which results in the formation of a pink patch (*salmon patch*); then the cornea may gradually weaken and bulge before the intra-ocular pressure, or it may ulcerate. Gradually, after many months, the cornea may clear more or less completely, but the patient is often left with

permanently damaged sight owing to concomitant iritis and choroiditis. The permanent teeth may show signs of congenital syphilis in the form of notching of certain teeth, which are narrowed at their cutting bases. The two upper central incisors are much the most usually affected (*Hutchinson's teeth*), but all the incisors may be notched. These characteristics are usually lost after the age of 20. The first molars are often dome-shaped, the cusps having fallen together from failure of the central pillar to mature (*Moon's teeth*).

The long bones may be affected in various ways. During the first few months syphilitic epiphysitis may cause signs simulating paralysis (*syphilitic pseudo-paralysis*) owing to the rapid loss of movement which occurs. Movement of the limb causes severe pain, which explains the apparent paralysis. The epiphysis is swollen, and occasionally definite separation occurs. Arthritis may be associated with epiphysitis, and the joint may suppurate. Between 5 and 18 years of age chronic synovitis affecting chiefly the knees, with swelling of joints but with slight pain or interference with movement, may be puzzling to diagnose unless syphilis is remembered.

Dactylitis occurring in the second year causes fusiform swelling of the proximal phalanges of two or more fingers, or, more rarely, toes. At a later period in childhood, between the ages of 8 and 14, chronic periostitis of long bones is apt to cause characteristic deformities, best shown in the tibiæ, which become shaped like sabre-scabbards.

The visceral and nervous affections of congenital syphilis are dealt with in other sections.

Diagnosis.—Syphilitic pemphigus occurs on the palms and is earlier than ordinary pemphigus neonatorum, and *Sp. pallida* can be found in the secretion. Ordinary erythematæ are brighter red, and associated with friction and moisture such as from wet napkins, while the syphilide is not necessarily accounted for by friction, or by moisture, and is associated with such signs as "snuffles" and chronic laryngitis.

Syphilitic epiphysitis is distinguished from true paralysis by the pain on movement and contraction of the muscles when the skin is irritated. It occurs earlier than scurvy or rickets, appearing about the third week, and is associated with the skin and mucous-membrane lesions of syphilis. It is well to remember that syphilis has been found to be responsible for many of the nutritional and mental disorders of childhood, and that it is advisable to investigate every obscure case with syphilis in view.

Treatment.—*Prophylaxis.*—In a classical experiment on man, Metchnikoff prevented the development of syphilis, after inoculation with virulent syphilitic virus, by rubbing the following ointment into the scarified area an hour after the inoculation :

Calomel	33
Lanolin	67
Vaselin	10

Probably a more effective method would be to steep the part for some minutes in 1 in 2000 iodide of potassium and mercury and then to rub in the above ointment. I have seen many failures from the use of such antiseptics as potassium permanganate and even lysol applied thoroughly a few minutes after exposure. It is well to remember in connection with prophylaxis by

disinfection that antiseptics do not act immediately, and that their effect is very considerably hampered by organic material. It is difficult, therefore, to understand how a thin film of potassium permanganate could destroy any organisms left on the surface after swabbing the parts.

During recent years prophylaxis by ingestion of Stovarsol tablets, or by injection of arsenobenzene compounds, has been advocated by many workers. Stovarsol, an arsenical preparation, is dispensed in tablets containing 0.25 gramme each. The person who has been exposed to infection takes four each morning before food for four successive mornings, and repeats the treatment in each of the following two weeks. When the injection method is employed, a short course of intravenous injections of "914" is given, much as indicated on p. 216. Considerable success from these methods has been reported, but they are opposed by a number of high authorities, chiefly on the grounds of the possibility of their merely masking symptoms. Both antiseptic applications and arsenical treatment employed as prophylactics may prevent the appearance of the primary sore but not the infection, so that those who have employed them should resort to tests afterwards, to make certain that no later sign of syphilis appears, e.g. a positive serum reaction.

The prevention of accidental infection of fingers, lips and other extra-genital parts resolves itself into measures to prevent the direct or almost direct contamination of abrasions with the virus from syphilitic persons who are in the earlier stages of syphilis. Such persons should be warned of the risk arising from sharing table utensils, crockery and house linen with others. They should not kiss others nor talk directly into people's faces, and articles which they have used should be dipped in very hot water. A further precaution is to keep open lesions smeared with an antiseptic ointment such as the Metchnikoff cream mentioned above.

The prevention of transmission to offspring is primarily a matter of preventing infection of mothers. A man who has contracted syphilis should be advised to wait for at least five years before marrying; by that time the risk of transmission by sexual intercourse has usually gone, whatever the treatment. The period can be shortened by treatment, but this must be prolonged and thorough. A syphilitic woman is liable to convey the disease to her offspring throughout the child-bearing period. Efficient treatment of the mother before or during pregnancy will usually prevent the disease being transmitted, or, if the latter has already occurred, will go far towards curing the infant before it is born. Naturally, the earlier this treatment is commenced the more likely the success.

Curative treatment of syphilis.—The remedies most commonly employed for the treatment of syphilis are preparations of arsenic, mercury, bismuth and iodine. The first three are believed to destroy the parasites; the last to stimulate the tissues to clear away granulosomatous tissue.

"606," or dioxydiammoarsenobenzene dihydrochloride, was produced by Ehrlich in 1909. It is now sold as Salvarsan. Arsenobenzol (Billon), Arsenobillon, Kharsivan, Diarsenol, and Arsphenamine, according to the country of origin and the manufacturing firm. It is a yellow powder which forms an acid solution when dissolved in water. Addition of an alkali to this solution causes a precipitate which redissolves on addition of more alkali. Being liable to change on exposure to air, it is sold in sealed ampoules containing weighed amounts of this compound. Owing to the complexity

of its preparation for administration and the difficulties of this, the original "606" is now very little employed, and consequently special works should be consulted for details of its injection.

In order to obviate the inconvenience of administration which attaches to the use of "606," Ehrlich experimented to discover a compound having the same therapeutic properties but simpler to administer. The result was two preparations, one called "914," which was produced shortly after "606," and is now used very extensively. The other, "*Sodium salvarsan*," is "606" already converted to the sodium compound. It is a yellow powder which requires only to be dissolved in water and can be given much more concentrated than the original preparation. It is about two-thirds the strength of salvarsan and, in equivalent doses, is a more easily tolerated preparation than the original.

"914," or dioxydiaminoarsenobenzene monomethylene sulphonylate of soda, is now sold as Neosalvarsan, Novarsenobillon, Neokharsivan, Novarsan and Neo-arsphenamine. It is a yellow powder (containing 18 to 22 per cent. of arsenic) which is much more liable than salvarsan to become toxic on exposure to air, so that it must be administered very quickly after the ampoule has been opened and its contents dissolved. It is soluble in its own weight of water, in which it forms a neutral solution. The most usual method of administration is the intravenous. The dose, from 0.45 to 0.9 for adults (which corresponds to 0.3 to 0.6 of "606"), is dissolved in 2 to 5 c.c. of distilled water and drawn into a syringe. The syringe is armed with a fairly fine needle, and the point of the latter inserted into the vein, which should be distended as tightly as possible, by fastening an elastic band round the upper arm and making the patient grasp a roller bandage. A pull on the piston causes blood to flow back into the syringe when the needle is properly within the vein. The rubber band is released, the hand opened, and the piston pressed steadily home. "914" can also be given intramuscularly or into the deep subcutaneous tissues, the dose being dissolved in about 2 c.c. of water. Its therapeutic effect when administered in this form is undoubtedly greater than when injected intravenously. The injection may cause considerable pain, which may be immediate or come on 2 or 3 days later and last for about a week. More recently various preparations have been synthesised, which, in many respects, are similar to "914." Their great advantage is that they can be injected subcutaneously with very little discomfort to the patient. The best known in this country are Sulfarsenol, Kharsulphan, Metarsenobillon and Myosalvarsan. They are readily soluble in distilled water, and can be injected in a concentration of 0.6 gramme per c.c. of water intramuscularly or just over the fascia covering the glutei as follows. In the upper and outer quadrant of the gluteal region the skin and fat are pulled away from the underlying fascia, by grasping them with the thumb and fingers of the left hand, and a 2-inch record needle is entered obliquely at the base of the pyramid thus produced. The needle is made to under-run the fat so that its point may scrape on the fascia overlying the gluteal muscles. The charged syringe is fitted to the needle and the injection given fairly slowly. The site is then massaged with a pad of lint. A preparation known as Stabilarsan is a solution of the base of "606" in glucose. Stabilarsan is preferably given by the intravenous route.

Two preparations have been introduced by Kolle, the successor of Ehrlich. One, called Sulfoxyl-salvarsan, is a stable arsenobenzene preparation put up in ampoules already dissolved and ready for injection. The other preparation, known as Silbersalvarsan, is a combination of salvarsan and silver. It is an emery-coloured powder which forms a dark brown solution in water. It is well to dissolve in 8 c.c. water, and, after puncturing the vein, to draw about 2 c.c. blood into the syringe. The injection should be given much more slowly than neosalvarsan, otherwise the patient may suffer from vasomotor symptoms as noted below.

Therapeutic properties of arsenobenzene preparations.—All the arsenobenzene preparations mentioned above act more rapidly than mercury or bismuth. The greater certainty of cure is shown by the fact that unequivocal second attacks of syphilis, formerly a great rarity, are now comparatively common, even in the experience of those who understand the difference between recurrent and new chancres. Kolle's silver salvarsan appears to be about twice as powerful in immediate therapeutic effect as "606," and can consequently be given in much smaller doses. Sulfoxyl-salvarsan is slower in action. It is used for old-standing cases, in courses of three injections of 8, 10 and 12 c.c. at intervals of 2 to 3 weeks. Stabilarsan appears to be slow in action as judged by the disappearance of *Sp. pallida* from open early lesions after its injection, but its effect seems to be more profound than that of "914." When the results of an intramuscular or deep subcutaneous course of neosalvarsan are compared with those of an intravenous of any compound there is little doubt that the advantage rests with the intramuscular or subcutaneous method, and it is reasonable to expect that the same will be found of the closely similar preparations sulfarsenol, kharsulphan, metarsenobillon and myosalvarsan. Sufficient is not yet known of silver salvarsan and sulfoxyl-salvarsan to indicate their position in regard to permanence of effect, but considerable evidence has been produced to show that the silver arsenobenzene preparations are valuable in syphilis of the nervous system.

Owing to convenience of administration the worker will probably choose, for consulting-room practice, "914," stabilarsan, or one of the silver preparations for intravenous, and sulfarsenol, kharsulphan, metarsenobillon or myosalvarsan for subcutaneous treatment.

Toxic effects of arsenobenzene remedies.—These compounds all tend to damage capillary endothelium. In patients who have died as a result of overdoses, or of idiosyncrasy, there have been found blockage of cerebral capillaries with small hæmorrhages around; hæmorrhagic nephritis; hæmorrhage into lung capillaries; submucous petechiæ and ecchymoses in the stomach and bowel; and, in a comparatively few cases, degeneration of liver cells amounting to a condition like that found in acute yellow atrophy.

Clinically, toxic effects are manifested by one or more of the symptoms enumerated below. The list is a comparatively long one, but most of the symptoms are so mild, infrequent, or preventable as not to preclude the routine use of these remedies. In roughly chronological order they are as follows:

1. *During or immediately after the injection.*—(1) Vasomotor disturbances, also known as anaphylactoid symptoms or minor nitritoid crises; (2) urticaria; (3) syncope; (4) pain in the gums and teeth.

2. *Following the injection usually in a few hours, and occurring generally on the same day.*—(5) Rigor, rise of temperature, and headache; (6) vomiting, diarrhœa, pain in the back and cramp in the legs; (7) herpes (labialis or zoster).

3. *At various times from a day or two to a month or longer after a single injection or a course of injections.*—(8) Albuminuria; (9) stomatitis; (10) chronic headache; lassitude; loss of appetite, weight and sleep; (11) erythema and dermatitis; (12) jaundice; (13) severe cerebral symptoms.

The *vasomotor symptoms* simulate very closely those of anaphylaxis. The face becomes flushed, and the tongue and lips may swell; there may be respiratory distress, and the patient may become unconscious. Often a severe attack is followed by more or less generalised *urticaria*. As a rule the symptoms last for about half an hour, but in rare cases recovery is not complete for a number of hours. Some patients are peculiarly susceptible. In others the symptoms may be produced by imperfect preparation of the remedy for injection or too rapid administration, as they depend on the physical state of the solution on entering the circulation. As measures of prevention, solutions of "914" should not be given concentrated if the preparation does not dissolve perfectly in practically its own weight of water; sodium salvarsan and silver salvarsan, if given in concentrated solution, and stabilarsan, should be injected slowly. The treatment usually employed is to inject 10 to 15 minims of adrenalin chloride (1 in 1000) hypodermically. A good method of prevention is that recommended by Sicard. The tourniquet is retained during the injection and may preferably be kept on the upper arm for some minutes (even 10 to 15) after removal of the needle. In the latter case a pad should be held closely to the bend of the elbow to prevent a hæmatoma. *Syncope* is usually mental, unless it precedes vomiting. *Pain in the gums and teeth* is probably vasomotor. The *peculiar taste in the mouth*, of which some patients complain during the injection, is a very common symptom when concentrated solutions are given.

Rigor, rise of temperature and headache are very rarely severe, but are commoner after first than after subsequent injections. *Diarrhœa* and *vomiting* are not frequent unless there has been an error in technique, or the patient has been indiscreet in his dietary. Quite often they are followed by *herpes*. Usually these symptoms have all disappeared by the next day. They are prevented to some extent by taking care that the patient has fasted for 2 hours before the injection.

Albuminuria very rarely causes any anxiety. *Stomatitis* is not often attributed to arsenobenzene remedies, but these undoubtedly seem to increase the tendency to this complication which is manifested by patients on mercurial, or bismuth treatment. *Chronic headache, lassitude*, etc., are symptoms of intolerance displayed by a few patients, and indicate the necessity of a rest from treatment.

Various *skin affections* may occur besides the urticaria and herpes mentioned above, and may be very serious. The mildest is some slight itching which quickly passes off. Some patients show a transient and limited erythema, but in a small minority a punctiform erythema quickly spreads over the body, is accompanied by most intense itching, and often then passes on to exfoliative dermatitis. The incidence of dermatitis depends largely on the intensity of the treatment. Generally speaking, a male adult of

average build will easily tolerate 4 grammes of "914" in doses of 0.45 to 0.75, or the equivalent of this in other arsenobenzene remedies, spread out over a period of 57 days, but if this period is shortened the percentage of dermatitis increases noticeably. A careful look-out for signs of skin irritation will often supply timely warning of the idiosyncrasy and, by preventing the administration of more arsenobenzene, will save the patient from a severe attack. The treatment of exfoliative dermatitis following arsenobenzene injections is often troublesome on account of the generalised exfoliation and the local pustulation and eczema. Generally, the patient should be in bed and well protected. The injection of sodium thiosulphate, which is now sold for the purpose in ampoules containing measured amounts, has proved to be very useful in aborting the toxic effects of arsenobenzene, bismuth and mercury. The dosage for general use is 0.45, 0.6, 0.75 and 0.9 gramme, dissolved in 5 to 10 c.c. water, and injected intravenously or intramuscularly every other day. On intervening days an intravenous injection of 25 c.c. of a 25 per cent. solution of glucose is valuable. The injections may be supplemented by pulv. sod. thiosulph. gr. xxx, dissolved in half a tumblerful of water, taken each morning before food. The diet should be simple, containing large quantities of bland liquids, and should not include eggs and meat. Locally, calamine lotion is soothing and an occasional bran bath is valuable, but careful precautions should be taken against chill, as these patients are very prone to pneumonia.

Jaundice following injections of arsenobenzene preparations appears to have become much more common in recent years, and a voluminous literature on its aetiology has accumulated in all countries without any definite consensus of opinion having been arrived at. In the very great majority of cases the type is mild, with clayey stools and highly coloured urine. Occasionally it is much more serious, with severe epigastric and hepatic pain, restlessness and delirium, followed by death. Broadly, the changes found in these rare cases have been extensive degeneration of liver cells with round-celled infiltration of the supporting connective tissue, multiple subserous hæmorrhages, and frequently hæmorrhages into lung alveoli. Either type may occur during a course of injections or be delayed for many months afterwards. In respect of the delay in onset, as in some other features, the fatal type of jaundice strongly resembles trinitro-toluene poisoning. The exact part played by arsenobenzene in the production of jaundice is uncertain, but the weight of evidence seems at present to favour a connection between the amount of arsenobenzene administered as routine in a given time and the proportional incidence of jaundice, the more concentrated the course the higher being the percentage of jaundice. A feature of the fatal type of jaundice which has been noted in this and other countries is its tendency to occur in limited outbreaks which bear no apparent relation to changes in technique or brand of the remedy employed. This feature lends some support to the theory, held by some, that besides arsenobenzene an extraneous agency (bacterial infection?) plays a part in the causation.

For the *prevention* of jaundice, besides regulation of the dosage, the diet should be fairly generous in carbohydrates and somewhat restricted in fats and proteins. For treatment, besides reduction of the diet to slops, daily intravenous injections of 25 to 50 or more c.c. of a 25 per cent. solution of glucose are useful.

Severe *cerebral symptoms*, with headache followed by mental confusion, epileptiform convulsions and coma, ending in death in a large proportion of cases, are now very rare, thanks to the moderate doses with which treatment is usually commenced. One patient, whom I saw in the comatose condition, was restored within half an hour by phlebotomy to 20 ounces, the removal of 15 c.c. of cerebro-spinal fluid, and the injection of 4 c.c. of adrenalin chloride 1 in 1000. Other workers have since been equally successful by this means. The treatment should be applied at once, and the lumbar puncture should be repeated if the symptoms continue. *Thrombosis* of the injected vein is more apt to follow injections of silver salvarsan and of stabilarsan. It is usually prevented by taking the precaution to clear the needle of solution before withdrawing it, by aspirating a few c.c. of blood into the syringe.

Jarisch-Herxheimer reaction.—A temporary effect of these, as of other antisyphilitic remedies, may be to increase the intensity of the syphilitic process. This may be important when an artery supplying some vital organ is already partly blocked; then the increase in the severity of the process may result in a complete blockage which may be disastrous, as when a coronary artery becomes obstructed, or the patient develops hemiplegia, or dies of obstruction of the basilar artery. Such cases are very rare.

Neuro-recurrences.—Though not strictly a direct effect of arsenobenzene treatment, paralysis of various cranial nerves, especially the seventh and eighth, became more common shortly after its introduction. These phenomena have been proved to be syphilitic recurrences and due to the small amount of treatment given in the early days of "606." Since it has been recognised that much more than 1 or 2 doses of "606" is necessary for the cure of syphilis, neuro-recurrences have become comparatively rare.

Precautions recommended in treating patients with arsenobenzene compounds.—In the case of sufferers from advanced Addison's disease, bleeders, and those on the point of death from severe visceral disease, these remedies are contra-indicated.

In all cases where intravenous injections are employed it is advisable for the patient to fast for 2 hours beforehand. In my own centre the administration of glucose ℥xiv , sod. bicarb. gr. xv , ol. limonis ℥j , aq. ad. ℥iii half to 1 hour before each injection, has appeared useful in preventing jaundice. The principle is that a well-fed liver will not be poisoned so easily as a starving one, and it is remarkable how very few private patients develop jaundice. Other methods of prevention of this and other toxic effects of arsenobenzene consist in scrupulous care over technique, particularly in avoiding contact of solutions with alcohol.

In visceral disease of a less severe type than is mentioned above, in alcoholism, and when the patient is prone to such skin affections as eczema and severe seborrhœa, it is advisable to begin with a dose of 0.15 to 0.3 gramme of "914," and to increase the intervals in the outline of treatment given below. The same applies to patients suffering from syphilis of the brain, cord or viscera when there is reason to fear an exacerbation of the process. In diabetes mellitus it is necessary to be very cautious, as arsenobenzene increases the blood sugar, and the patient should be watched carefully by some one experienced in the administration of insulin.

In all cases the commencing dose should be moderate. 0.45 gramme of "914" or stabilarsan, or 0.15 gramme of silver salvarsan for an adult male

who is otherwise healthy. The intervals between doses should be spaced in a way which has proved to result in a very low proportion of toxic side-effects. I have found in the case of men that, when 6.0 grammes "914" are compressed into less than a 92 day course, the incidence of such toxic side-effects as dermatitis increases noticeably. The patient should be watched carefully through the course for signs of intolerance. This precaution may not absolutely prevent severe side-effects, but such as do develop will usually be much milder than when no notice is taken, for example, of an erythema, and the treatment is continued to the end of the course.

Mercurial preparations.—Mercury was formerly the sheet-anchor in the treatment of syphilis. Its action is much slower, however, than that of the arsenobenzene compounds, and when it is used alone relapses are frequent whilst the patient is actually under treatment. The great advantage of mercury is that it can be kept almost continuously in the circulation, so that the action is maintained after the dose of arsenobenzene has been excreted until it is safe to administer another arsenobenzene injection. To ensure the certain destruction of all the parasites, it seems to be necessary that an anti-syphilitic remedy should be present constantly in the body fluids for a period of many months.

Methods of Administration.—The *oral method* is much favoured, but is apt to cause gastro-intestinal disturbance, and is exposed to the risk of failure through the patient's forgetfulness. I employ it only in those cases where the patient cannot take injections or inunctions and also when, a large amount of arsenobenzene and mercurial treatment having been given, the patient cannot continue injections or remain under close observation. Favourite preparations are—(1) *Hydrargyrum cum creta*, grs. i to ij; (2) *hydrargyri iodidum viride*, gr. $\frac{1}{8}$ to $\frac{1}{4}$; (3) *hydrargyri perchloridum*, gr. $\frac{1}{6}$; (4) *hydrargyrum tannicum oxydulatum*, gr. i; (5) *pil. hydrargyri*, grs. i to iiij; (6) *liq. hydrargyri perchloridi*, 5 $\frac{1}{2}$ to i, often prescribed in a mixture with potassium iodide. The first five of these are usually given in pill form, often combined with a little opium, e.g., *pulv. ipecacuanhæ compositus* grs. i to ij, or *extractum opii* gr. $\frac{1}{2}$, to counteract the irritant effect. It is a good plan to ring the changes on these preparations until one is found which does not upset the patient. Generally speaking, the best plan of administration is to give courses of a month or six weeks, gradually increasing the daily intake of mercury until slight signs of stomatitis appear, and then reducing the dose. After the first and second courses rests of a week are given, and at the end of the third the interval is one month, after which the series of three courses is repeated. The length of time over which this treatment is prolonged depends greatly on the amount and character of the previous treatment.

Inunction.—This is a valuable method of administering mercury, but must be carried out by a skilled rubber, and has the inconvenience of soiling the skin and clothes. On successive days 5 to 10 grammes of 33 $\frac{1}{3}$ per cent. mercurial ointment are rubbed for twenty minutes into thighs, calves, arms, chest and back, a bath being taken on the sixth day and the cycle restarted on the seventh. The number of rubbings varies from 60 to 200 in a course, the length of a course depending on the patient's tolerance, which is judged by the state of the gums, the weight and the general well-being.

Intravenous injections are rapid in effect, but very apt to give rise to toxic symptoms; they appear to me to have the further disadvantage that the effect is not sustained. The usual preparations employed are the cyanide and the perchloride, in doses of 1 c.c. of the 1 per cent. solution daily or on alternate days to a total of twenty or thirty.

For *intramuscular injections* both soluble and insoluble preparations are employed. Among the *soluble* preparations are the biniodide (1 per cent. solution) in doses of 1 c.c., the bibromide, the benzoate and the perchloride, the last being made up as follows :

Sod. chlor.	gr. iv.
Aq. destill.	400 m.

Dissolve, filter and add hydrarg. perchlor. gr. viij. Dose, 5 to 10 m.

The soluble preparations are more rapid in effect, but this is not sustained. They have the further disadvantage of having to be given daily or on alternate days.

The *insoluble* preparations most commonly employed are mercury in fine subdivision, calomel and mercury salicylate. Suspensions of these remedies ready for use are sold by most chemists. The doses usually employed are: mercury, 1 to 1½ grs.; calomel, ½ to ¾ gr.; salicylate, 1½ to 2 grs. Calomel causes more pain than the other two, and my own preference is for mercury in fine subdivision. The advantages of the insoluble preparations are that, on account of the slow absorption, enough mercury can be given in one injection to last a week, and that the effect is sustained.

The technique of intramuscular injections is simple. The site usually chosen is the upper and outer quadrant of the gluteal region. A needle 2 inches long is introduced, almost to its full length, perpendicularly to the skin surface. The base is examined to see that no blood is oozing from it, the syringe is applied, the piston pulled upon to see that the needle point is still not within a vein, and the piston is then pressed home. The needle having been withdrawn, the site is well massaged with a ball of cotton-wool. Before an insoluble preparation is drawn into the syringe, the suspension should have been well mixed, either by stirring with a glass rod or by energetic shaking of the bottle.

Toxic effects of mercury.—These are stomatitis, nephritis, colitis, general malaise and dermatitis.

Stomatitis can usually be prevented by care. The patient's teeth should be set in order before starting the course, and he should brush his teeth night and morning; the tooth brush should be kept in an antiseptic solution, such as chloramine T, 0.5 to 1 per cent. Potassium chlorate is useful, and may be incorporated in the dentifrice. If the gums become sore, the mercury must be stopped and more energetic treatment applied to the mouth. Lozenges of potassium chlorate to suck, and swabbing with peroxide of hydrogen, followed by the application of collosol argentum, or of a mixture of liq. arsenicalis 1, vinum ipecacuanhæ 1, and spiritus vini rectificatus 2 parts, usually suffice to restore the gums to a healthy condition. An astringent mouth wash should be employed and injections given of sodium thiosulphate. (See p. 210.)

Nephritis rarely results from the moderate doses of mercury now em-

ployed, but the irritant effect of mercury on the kidneys should be remembered in cases where these organs are already diseased.

Colitis is extremely uncommon as the result of the ordinary mercurial course of treatment. *General malaise* is apt to result from pushing mercury too freely, and it is always advisable to keep a close watch on the patient's weight and general condition. *Dermatitis* as a result of mercurial treatment alone is very rare.

Bismuth preparations, introduced by Sazerac and Levaditi in 1921, have rapidly acquired a prominent position amongst anti-syphilitic remedies, and seem likely to supplant mercury wherever the intramuscular, or deep subcutaneous, route of administration is practicable. Bismuth is tolerated better than mercury, in doses which can be administered with at least equal safety, and acts more rapidly than the older remedy, while a course of bismuth injections goes farther towards eradicating the disease than does a corresponding course of mercurial injections. Some workers assert that bismuth is equal in effect to arsenobenzene, but the majority opinion is that it is a substitute for mercury, not arsenobenzene. The toxic effects of bismuth are somewhat similar to those of mercury. The first sign of saturation is a slaty-blue line at the margins of the gums, particularly at the incisor teeth. If the remedy is continued, the buccal mucous membrane may become stained, and aphthous stomatitis supervene. If the remedy is pushed still farther, gangrenous stomatitis may result. The early bismuth blue line may persist for many weeks after suspension of the remedy. Albuminuria may result from over-dosing, but disappears quickly if the remedy is suspended as soon as it is noted. Colitis is uncommon, but certain subjects may complain of depression of spirits and insomnia, which may easily be attributed to other causes than bismuth poisoning. Generally, however, bismuth gives rise to less trouble on account of toxic effects than does mercury. The metal can be administered in a large variety of forms, and the number of preparations on the market, each with a different trade name, is legion. The great majority resolve themselves into solutions, or suspensions, of (1) the tartro-bismuthate of potassium and sodium, which was the original preparation used by Sazerac and Levaditi and contains about 50 per cent. of metallic bismuth; (2) the hydroxide (bismuth content about 70 per cent.); (3) the oxychloride (bismuth content about 80 per cent.); (4) iodobismuthate of quinine (bismuth content about 20 per cent.); and (5) precipitated bismuth. The rapidity of action depends on the rate of absorption, and this is quickest in the case of solutions of the tartro-bismuthate. As to the others, it is at present difficult to say, but watery suspensions are more quickly absorbed than oily. The eventual effect depends very largely, as in the case of mercury, on the amount of metallic bismuth introduced into the tissues. The choice of preparations depends on these facts and on the local reaction following injections. The solution of tartro-bismuthate causes a fair amount of smarting, and appears to have been largely supplanted by kindlier preparations. The iodobismuthate is too bulky for convenience, and my own preference is for the oxychloride or the salicylate. Any one of these is usually tolerated perfectly, causing little or no pain at the site of injection. Opinions differ as to the dosage, some giving a course of 10 to 15 injections, totalling from 1.0 to 1.5 grammes of metallic bismuth; others, very much more. I have found that 0.1 gramme per week for a course

of 10 injections is usually tolerated well by the average adult male. The weekly dose can be administered in 2 or 3 injections, but I have usually found it convenient in average cases to inject once, namely, at the same time as the arsenobenzene injection is given. There are experimental grounds for believing that the presence of another metal in the circulation at the time an arsenobenzene preparation enters it assists the effect of the arsenobenzene, so that, apart from reasons of convenience, the simultaneous injection of arsenobenzene and bismuth appears likely to have the advantage of affording better results than when a course of bismuth (or mercury) precedes, or follows, one of arsenobenzene. An additional reason for administering bismuth (or mercury) at the same time as arsenobenzene is that this procedure seems to be attended by fewer neuro-recurrences.

Iodine preparations promote the resolution of syphilitic processes and are most useful in the later stages. The tissue reaction is qualitatively the same in all stages, however, and there are grounds for supposing that the syphilitic infiltrate tends to bury the parasites, making them inaccessible to anti-syphilitic remedies, so that there is a use for iodine preparations in all stages. Usually I have given them for short periods between courses of treatment by arsenobenzene and mercury or bismuth, on the principle of preparing the ground for the further action of the more definitely specific remedies. The favourite preparation is potassium iodide, in doses of 5 to 30 grains twice daily. It may cause gastro-intestinal disturbance, even when given very dilute in water, and is then better tolerated if made up in a cent. per cent. solution and the dose dropped into milk. The depressing effect of potassium iodide is overcome by giving it with *nux vomica*. Many proprietary preparations are advertised as superior to potassium iodide, but they should be reserved for cases where the older preparation cannot be tolerated. Sodium iodide may be given intravenously.

General management of syphilis.—The main principles to be observed in the treatment of syphilis are—(1) To begin as early as possible, before the parasite has become buried in the sclerosed primary sore or entrenched in comparatively inaccessible regions, such as the central nervous system; (2) to continue as long as experience shows that there is a possibility of the patient relapsing if treatment ceases; (3) to exploit the patient's natural resistance, by maintaining his general health in the highest possible condition.

Since the decision as to cure has to be postponed for some years after suspension of treatment, and relapse cases are particularly difficult to cure, it is better to treat all cases as if they were of the resistant type, even at the risk of overtreating some. Too much reliance is placed at present on a negative Wassermann reaction as an indication for suspension of arsenobenzene treatment, and I do not believe in continuing only with mercury after the reaction has become negative. Mercury is a slowly acting, comparatively feeble anti-syphilitic remedy, and if arsenobenzene remedies had not come into use, the two years' treatment formerly considered sufficient in this country would long ago have been prolonged to four or five as in other countries.

In all cases of primary sore it is very important to apply local treatment to destroy the organisms *in situ*; otherwise they may escape the remedies circulating in the blood. It may be possible to remove the sore by circumcision, or to destroy it with a cautery. Failing this, the sore may be rubbed

with 30 per cent. calomel ointment, or injected with a solution of "914" (say, 0.15 gramme in 0.5 c.c. water).

The programme of treatment of ordinary cases of syphilis in men of average weight without clinical manifestations of disease of the central nervous system or of any viscus which has been followed in the St. Thomas's Hospital V.D. Department from early in 1920 until a few months ago is as described below; and following it is a summary of the results which it has afforded.

For the sake of brevity the arsenobenzene preparation is referred to below as "914," but, instead of "914," stabilarsan may be given in corresponding doses intravenously, or, using one of the preparations mentioned above as suitable for the purpose, the route (which I prefer) may be deep subcutaneous or intramuscular. Another alternative to "914" is silver salvarsan, given intravenously, in doses approximately one-third, or slightly over this fraction, of those of "914." For women the dosage of the arsenobenzene preparation is reduced according to the weight of the patient, and does not ordinarily exceed 0.60 gramme "914."

The dosage of bismuth (Bi) is given in terms of metallic bismuth.

FOR SERO-NEGATIVE PRIMARY CASES.

- (1) Three injections of 0.45 gramme "914" intravenously, with 1 gr. Hg in mercurial cream or 0.3 gramme Bi intramuscularly at weekly intervals.
- (2) 2 weeks' rest.
- (3) Two injections of 0.60 gramme "914," with Hg or Bi as above, at weekly intervals.
- (4) 2 weeks' rest.
- (5) Two injections of 0.75 gramme "914," with Hg or Bi as above, at weekly intervals.
- (6) 3 weeks' potassium iodide, gr. v t.i.d. the first week; gr. viiss t.i.d. the second week; gr. x t.i.d. the third week.
- (7) Three injections of 0.75 gramme "914," with Hg or Bi as above, at weekly intervals.
- (8) No treatment for 5 weeks.
- (9) 3 weeks' potassium iodide as in (6).
- (10) Repeat (1) to (7).

FOR SERO-POSITIVE PRIMARY CASES.

- (11) As in (1) to (10) above.
- (12) No treatment for 10 weeks.
- (13) Potassium iodide as in (6) for 3 weeks.
- (14) Three injections of 0.60 gramme "914," with Hg or Bi as above, at weekly intervals.
- (15) No treatment for 2 weeks.
- (16) Two injections of 0.75 gramme "914," with Hg or Bi as above, at weekly intervals.

FOR SECONDARY CASES.

- (17) As in (1) to (16) above.
- (18) No treatment for 10 weeks.
- (19) As in (14) to (16) above.

FOR CASES LATER THAN SECONDARY.

(20) A series of courses as in (1) to (5), with intervals of 2 to 3 months between courses, potassium iodide being taken for 3 to 4 weeks in each interval.

The results of the above forms of treatment have, on the whole, been good. In the sero-negative primary cases which received the prescribed two courses and were observed afterwards for periods ranging from three months to 7 years, there were no relapses. In similar cases which received a little less than the prescribed amount, there were approximately 10 per cent. of relapses. In sero-positive and early secondary cases, the prescribed treatment was followed by approximately 10 per cent. of relapses.

In order to improve these results the treatment was for some months intensified by increasing the total amount of arsenobenzene treatment by approximately 50 per cent. But, although every dose of "914" was dissolved in 10 c.c. of a 10 per cent. solution of sodium thiosulphate, this procedure was followed by too great an incidence of jaundice and dermatitis.

It seems clear that it is impracticable to make the individual course much more intensive than as outlined above, and the writer, like others, is testing courses on various lines to obtain better permanent results than those mentioned. It is not yet possible to report definitely on any of these courses.

Serologically intractable cases.—Even in the sero-positive primary stage a small proportion of cases occurs in which the serum reactions remain positive in spite of prolonged treatment on lines commonly practised hitherto. This intractability increases with the age of the disease, until in cases of 2 years' duration or more a very high proportion are what is commonly termed Wassermann-fast. Some of these become negative when changed over to treatment by mouth after receiving a number of courses of injections, but a more hopeful method, the practice of which is increasing, is to combine metallic treatment with pyro-therapy. It has arisen largely from the good results obtained by malarial inoculation in G.P.I. As an example of this form of treatment may be mentioned the routine practice of Finger in quite early cases which show signs of intractability. Finger gives first 3 grammes "914" in doses of 0.3 to 0.45 at 5-day intervals, then inoculates with malaria and allows 10 paroxysms to occur before stopping the malaria with quinine. After this, commencing on the day of the last paroxysm, he gives another 3-gramme course of "914." His results, as reported, are far superior to those following the ordinary methods of treatment. As a substitute for malaria, which is troublesome and debilitating, may be mentioned the use of intravenous injections of typhoid vaccine and intramuscular injections of milk and various other pyrogenic agents. These have the advantage of being more convenient and of causing less debility, but so far those employed have not proved so successful as malaria. At the time of writing there is considerable activity in this field of medicine, and the writer would recommend readers to study its progress.

The treatment of syphilis of the viscera and central nervous system is considered elsewhere.

Before suspending treatment the blood and cerebro-spinal fluid should be

negative. After suspending treatment the patient should be put under observation, being examined clinically once a month, and by blood test every 3 months for a year. At the end of the year both blood and cerebro-spinal fluid are examined a week after a provocative injection of, say, 0.45 gramme "914." During the second year the blood tests are at intervals of 6 months, the provocative injection and examination of cerebro-spinal fluid being repeated at the end. As a rule it is not advisable to allow a patient to marry until after 5 years from infection and after remaining free from all signs, clinical and serological, for at least 2 years following suspension of all treatment.

Pregnant women are treated on much the same lines, the dose not exceeding 0.6 gramme. On account of the susceptibility of the kidneys, it may be advisable to withhold mercury or bismuth for the first few injections until it is seen how the injections are tolerated. Treatment may be continued almost to the end of pregnancy, a careful watch being kept on the kidneys throughout.

Syphilitic infants.—The treatment of syphilitic infants is carried out on the same principles as that of adults. When the mother has been treated throughout pregnancy, it is still advisable to continue treatment of the infant for at least a year. When treatment commences only after birth the child is in a position analogous to that of an untreated adult many months after infection, and its treatment should continue for at least 2 years.

In most cases it will be found convenient to inject the arsenobenzene preparation intramuscularly. If the intravenous route is preferred, the vein usually chosen is the external jugular or one in the temporal region. A good commencing dose is 0.05 gramme, though Findlay recommends 0.10 to 0.15 for an infant of 1 to 2 months, increasing to 0.2 to 0.3 in older children.

Mercury is given in the form of hydrargyrum cum creta by the mouth : as mercurial cream intramuscularly in doses of $\frac{1}{8}$ to $\frac{1}{2}$ grain according to age, or by inunction. Probably the most convenient and efficacious method is by inunction. A piece of mercurial ointment the size of a pea is rubbed, as Findlay recommends, for 15 minutes on successive days, into abdomen, back, one axilla, other axilla, one groin and other groin in turn, returning to the abdomen on the seventh day. This is continued for many months. Bismuth injections are well tolerated, the dosages being calculated according to the weight of the patient.

Such a tonic as *syrupus ferri jodidi* should also be administered.

YAWS

Synonyms.—Frambœsia ; Frambœsia tropica : Pian ; Bubas ; Parangi.

Definition.—An infectious granuloma, contagious and inoculable, due to the *Treponema pertenue* (Castellani), and characterised by fever with a peculiar eruption of raspberry-like papules.

Ætiology.—The disease is common in many parts of the tropics, especially in the West Indies, Fiji, Ceylon and Java. The natives in these parts are affected. It is very rare in Europeans. Children are specially liable. Both

sexes may be attacked. The cause is the *Treponema pertenue* (Castellani), an organism resembling closely the *Spirochaeta pallida*. The disease bears many analogies to syphilis, but is generally not venereal in origin, the infection taking place through abrasions or cuts in the feet, hands, etc.

Pathology.—There are no lesions in the organs as in syphilis, and the arterial walls do not show endarteritis. The papules have the structure of an infective granuloma, a stroma of fibrous tissue with granulation cells, plasma cells, etc.

Symptoms.—Some authorities state there is a definite primary sore; but certainly in most cases this does not occur. An incubation period precedes the eruption. In this stage the patient complains of vague pains, often worse at nights, in the bones and joints, and headaches with temperature also now occur. The eruption then appears, the skin loses its gloss and becomes dull and scaly, papules, at first the size of a pin head, come out over the body, and gradually enlarge until they become the size of peas or small nuts. Coalescence of several of them may form large masses. The skin over the papules desquamates, leaving a reddish warty-like surface exposed, which closely resembles a raspberry. A whitish-yellow fluid oozes out of the papules, and this drying up forms a yellow scab or crust which if left alone becomes heaped up into a conical mass, like a syphilitic rupia. If the scabs be removed, new crusts form again and again. The face is a favourite site of the papules, as also the anus and genitals; the body is also affected and, in some instances, the mucous membranes do not escape. Successive crops may continue to come out, each new exacerbation being accompanied with a fresh rise of temperature and pains in the limbs. The number of the papules varies, they may be few in number, while in other cases the skin is covered with them. Finally, the papules dry up, shrink, and fall off, leaving a lighter coloured area than the normal skin in natives, a pigmented area in light-skinned races.

Course.—The duration of the disease varies considerably; 6 weeks may see the finish of all signs, whereas in other instances the illness may continue for a year or more.

Complications.—In long-standing cases other symptoms, which are probably due to the *T. pertenue*, may appear—periostitis, inflammation of the joints, teno-synovitis, chronic ulcers, caries of bone and ulcerations of the palate and mouth. These are looked upon as manifestations of tertiary yaws, and are frequent in the Fijian variety of the disease. Even later lesions such as tabs have been ascribed to the *T. pertenue* by Fijian observers. Such lesions very frequently occur amongst the Fijians, amongst whom syphilis is said to be absent, and this is, of course, a strong point in favour of such symptoms really being due to yaws.

Diagnosis.—This is easy, the eruption being very characteristic. Syphilis and yaws may exist together, and this complicates the diagnosis. Wassermann reactions may help. The disease is very common in young children in the West Indies, and this is to be borne in mind when diagnosing their different complaints.

Prognosis.—This, on the whole, is quite good. Children may die of it sometimes, as may also debilitated adults. Deaths, however, considering the enormous numbers of people attacked, are rare.

Treatment.—Close contact with yaws cases should be avoided, and

infected individuals, if possible, should be placed in yaws hospitals, a class of building which exists in all heavily infected yaws areas (West Indies, for example).

Salvarsan or neo-salvarsan is a specific for the disease. One injection of 0·3 grammes is often sufficient to stop the disease at once. It is comparatively rare for a second injection to be required. The treponema of yaws is more easily destroyed than that of syphilis. Recently bismuth has also been used with success and has the advantage of being cheaper than salvarsan.

G. CARMICHAEL LOW.

D. PROTOZOAN INFECTIONS

MALARIA

Definition.—A protozoal infection of man, associated in most cases with definite attacks of regular periodic fever, enlargement of the spleen and anæmia. The disease is carried by anopheline mosquitoes.

Ætiology.—Malaria occurs generally throughout the tropics and the sub-tropics, and even in temperate regions. One or two tropical islands are free from it. Barbados, which used to be free, has recently become infected. All races are liable; in endemic areas the infection is commonest in children, adults gradually acquiring a certain degree of immunity. Both sexes suffer equally. The parasite of malaria belongs to the *Sporozoa*, one of the chief groups of the Protozoa, sub-order *Hemosporidia*, genus *Plasmodium*. There are three leading forms in man. Benign tertian, B.T., is due to the *Plasmodium vivax*, Quartan malaria to the *P. malaria*; and malignant malaria, M.T., to the *P. falciparum* (*Laverania malariae* or *præcox*, according to some).

These parasites undergo two cycles, one in the blood corpuscles of man, the other in the tissues of the mosquito.

Human phase (endogenous, asexual, or schizogony). The sporozoites inoculated by the mosquito pass into the blood stream and enter the red blood corpuscles, where they change into little rings (signet ring), which gradually grow, develop more protoplasm and black pigment, and finally—B.T. and Quartan—fill the corpuscular envelope. The pigment then collects in the centre and the protoplasmic mass divides into a number of spores (sporulating body, rosette or schizont). The envelope now gives way, and the spores (merozoites) are scattered in the plasma. They quickly penetrate new red corpuscles and the cycle begins again.

Mosquito phase (exogenous, sexual, or sporogony).—When the sporulation of the asexual cycle takes place, certain large forms, in benign tertian and quartan infections, which do not sporulate, are seen filling the corpuscles. These are the gametocytes or sexual forms. In malignant malaria, M.T., the gametes are crescentic. When taken up by mosquitoes of a suitable type these gametes undergo the following development. The crescents of the malignant form change into circular bodies—the gametes of the benign fevers are originally circular. From the males, flagella become detached (equals the spermatozoa of higher forms), and these, penetrating the female bodies,

fertilise them (sexual act, zygosis). The resulting body now elongates, becomes pointed at one end (travelling vermicle or ookinet), and penetrates the wall of the mosquito's stomach, where it comes to rest, again takes on a circular form, and proceeds to grow (oocyst); the oocysts become filled with numerous spindle-shaped bodies (sporozoites), and protrude from the wall of the stomach like little herniae or warts; finally, they rupture, and the sporozoites escape into the tissues and pass into the salivary glands. When the mosquito next bites man it inoculates him with the saliva, and, the sporozoites passing into the red blood corpuscles, start the infection. (See Human phase just described.)

At suitable temperatures this development takes about 10 days, and after inoculation there is an incubation period of another 10 days until the fever appears.

The mosquitoes of malaria.—It is not every anopheline mosquito which can carry malaria successfully. The chief carriers are *Anopheles maculipennis* and *A. bifurcatus* in Europe; *A. funestus* and *A. costalis* in Africa; *A. albimanus* and *A. argyrotarsis* in the West Indies; *A. culicifacies*, *A. turkhudi* and *A. maculipalpis* in India; *A. umbrosus*, *A. maculatus* and *A. minimus* in Assam, Burma and the Federated Malay States.

The sporulation of B.T. and quartan takes place in the peripheral blood as well as in the blood of the internal organs, that of M.T. practically always in the latter, the forms seen in the peripheral blood being the small rings and the gametocytes or crescents. The benign tertian parasites can easily be distinguished from the quartan by the following points. In the former the corpuscle is enlarged and pale, the pigment is in large amount, of a brownish black colour, and of a fine consistence; Schüffner's dots are present, and there are 12 to 20 spores in the sporulating body; in the latter, the corpuscle is of ordinary size, the pigment is very coarse and black, and there are only 8 to 10 spores geometrically arranged like the petals of a daisy.

Staining.—Films are made in the usual manner, and may be suitably stained by Leishman's or Giemsa's stain. These methods bring out the chromatin in the parasites and other fine points in the structure of the different species. The rings, compared to a signet ring, consist of a nucleolus (dark red), a vesicular nucleus, and the outer ring, the protoplasm (blue).

Pathology.—If the infection has lasted any length of time a certain degree of anaemia is present; the white cells are normal, or diminished in chronic cases. The large mononuclear elements are relatively increased 10 to 25 per cent. The pigment of malaria consists of black dust-like grains, or coarser particles, or agglomerations into irregular lumps. It is insoluble in strong acids, altered by potash, and dissolved by ammonium sulphide. It is formed from the haemoglobin, and is diagnostic of malaria.

Polycholia or excess of bile is present. This is due to the conveyance of the liberated haemoglobin, after the corpuscular destruction, to the liver, where it is converted by the liver cells into bile and other derivatives. It is specially marked in the bilious type of M.T. This explains the slight jaundice seen in malaria. The distribution of the sporulating forms in M.T.—the cause of the different clinical symptoms—in order of frequency, is as follows: Brain, lungs, spleen, bone-marrow, liver, heart and intestines.

On autopsy, the liver is plum-coloured, the spleen enlarged and of a slaty

colour (in acute cases blackish red with the pulp very soft), while the intestines and brain may show a leaden colour. These features are very characteristic and give the diagnosis at once. Malarial pigment is found in the different viscera, and parasites in large numbers, especially at the chief seat of sporulation. The cerebral capillaries in such cases may be absolutely packed with parasites, sections showing them mapped out by the contained pigment.

Symptoms.—**CLINICAL TYPES.**—*Quartan.*—This is a benign variety. (Benign is a term applied to those forms of malaria which do not exhibit dangerous or fatal symptoms, such as coma, etc. They may, however, produce a considerable degree of anæmia and consequent weakness, thus rendering the individual more prone to other infections, such as tuberculosis; but death primarily due to the fever is rare.) The geographical distribution is typically sub-tropical, though it does also occur in the tropics. It is difficult to eradicate completely from the system, and causes considerable anæmia if untreated, often associated with albumin in the urine. The spleen may be moderately enlarged. Single infections of the parasite give rise to fever every fourth day, every 72 hours (Monday, at 12 noon—Thursday, at 12). Double infections will cause 2 days' fever with 1 day clear (Monday, at 12—Thursday, at 12, one generation; Tuesday, say at 3, Friday, at 3, the other generation; Wednesday, clear), while treble infections occasion a rise of temperature every day. The classical features of ague are present—cold stage, hot stage, and sweating stage, the rigor corresponding in time to the sporulation in the blood. (See films taken at the time.) High temperatures are met with up to 107° F. even; 105° F. and 106° F. are quite common.

Benign tertian fever (B.T.).—This is chiefly met with in the sub-tropics (e.g. Salonika), though also fairly common in the hotter regions. If untreated it causes anæmia and weakness. The spleen and liver are often fairly large. A single infection causes fever every other day, e.g., every third day, every 48 hours,—Monday, at 12, for example; Wednesday, at 12. A double infection every day, the maxima on the 2 days generally being of different heights and occurring at different times. Monday, say at 12 noon, 106° F.; Wednesday, at 12 noon, 106° F.; Tuesday, at 4 p.m., 103 F.; Thursday, at 4 p.m., 103° F. The classical signs of ague are present (see above), the rigors often being very severe with high temperatures. The temperature begins to fall when the sweating appears, and reaches the normal or sub-normal (Intermittent fever). Quinine quickly causes the parasites to disappear from the peripheral blood, and stops the fever. The infection, however, is very difficult to eradicate completely, and relapses are very frequent, even during treatment.

Malignant tertian malaria (M.T.).—**Synonyms.**—*Æstivo-autumnal Malaria*; *Pernicious Malaria*; *Sub-tertian Malaria*. It is possible there is more than one species of malignant malaria, the Italians having described two quotidian varieties and one tertian. Possibly, however, these quotidians are simply double infections of a tertian, while in other cases several generations of a tertian in the blood at one time will produce an irregular type of fever.

There are three main types of febrile disturbance associated with this form of malaria. (1) A typical tertian temperature with fever every other day, 48 hours' interval; (2) quotidian fever, with a temperature every day

at the same hour; and (3) irregular remittent fever, closely resembling an enteric fever chart. In these latter forms none of the classical features of ague may be present. Malignant fevers quickly produce anæmia, and if untreated, with fresh infections superadded, cause a profound state of cachexia. Pernicious symptoms may also appear at any moment, and are due to the sporulation in certain capillary areas. Such attacks may simulate almost any disease in medicine. They are divided into Cerebral forms—coma, convulsions, apoplexy, aphasia, paraplegia, hyperpyrexia, meningitis, etc. Abdominal—gastric, choleraic, dysenteric, hæmorrhagic pancreatitis type, appendicitis and peritoneal type, etc. Cardiac—Syncope and various forms of disordered action of the heart. Sudoral. Respiratory—bronchitic and pneumonic types. Urinary—albuminuric type. A speedy recognition of all these forms is necessary, as death is apt to occur with great rapidity.

Complications and Sequelæ.—Rupture of the spleen may occur, but usually only after some definite trauma. After many attacks and reinfections of malaria, especially the malignant varieties, a condition termed malarial cachexia supervenes. This is characterised by jaundice of the conjunctiva, yellow skin, great enlargement of the spleen and liver, perhaps albuminuria and periodic attacks of fever. There is then a great liability to acquire other disease, such as tuberculosis.

Diagnosis.—This is easy if quinine has not been taken. The diagnosis is made by examining the blood for the characteristic parasites. They are, in the large majority of cases, found within a few minutes of making the film. Occasionally they are difficult to find, but repeated examinations will eventually show them. Where quinine has been taken reliance has to be placed on blood counts, differential especially, for evidence of large mononuclear increase, and on an examination for pigment in the leucocytes. A history of periodicity in the temperature is always helpful.

Prognosis.—This is good as regards life in the benign forms, but it must always be remembered that malaria is an infection difficult to remove completely—2 to 3 years even, after good treatment. In malignant forms, the death-rate will be in proportion to the skill of the investigator in diagnosing his cases. Speedy recognition of the complaint means speedy treatment and saving of life. Pernicious forms, if not seen quickly, almost all die. Malaria is one of the chief causes of death in the tropics.

Treatment.—Destruction of the breeding grounds of anophelines, by drainage, filling in of marshes, lakes, burrow pits along railways, etc., should be carried out thoroughly, while adult mosquitoes should also, where possible, be destroyed. Residents in the tropics should sleep under mosquito nets and inhabit mosquito-proof houses; quinine as a prophylactic is advantageous. A small prophylactic dose will not prevent infection if bites from infected mosquitoes be frequent, but if they be few and far between, it may be successful. James has recently pointed out the importance of taking the prophylactic dose in the evening, if possible one dose at dinner-time of 5 grains, and another about 11 p.m. or midnight. There will thus be enough quinine in the system to kill any sporozoites inoculated that night. A happy combination of all these three methods will be found to give the best results.

There are only one or two drugs of value in malaria, quinine, arsenic and plasmoguinine.

Since the Great War, much has been written regarding treatment by quinine, and difficulties have been introduced, especially as regards its administration. The matter is really quite simple. If a patient with malaria can take the drug by the mouth and absorb it, then give it by the mouth; if he cannot, it must be given either intramuscularly or intravenously. Both these ways are perfectly easy, if ordinary care be taken. The intramuscular method causes a degree of necrosis of the muscle at the site of injection, but this is of little importance if no sepsis have been introduced. Tetanus has been described as following intramuscular injections in the tropics, the idea being that tetanus spores are already in the body, and settle down and multiply in the necrosed area. This is possible. Intravenous injections can be given, and as a matter of fact ought to be given, in all pernicious cases. Deaths have been reported as following them, but whether the death was due to the malaria or to the drug is not always clear. The risk must be taken in grave cases.

As regards dosage, opinions vary, but 10-grain doses three times a day for the first 7 days or so are generally sufficient to stop the fever in most cases. Some prefer giving 5-grain doses every 4 hours, the total for the 24 hours being the same, namely, 30 grains. After the fever has fallen, 5 grains of the drug should be given every night and morning (70 grains per week) for 2, 3 or more months at a time to prevent relapses (anti-relapse prophylaxis). The salts of quinine to be employed are of importance; the bi-hydrochloride, on account of its solubility, is the best to use for intravenous and intramuscular injections and is administered in 10-grain doses. Smaller doses than this have been recommended, the suggestion being that these should be repeated every 2 or 3 hours, but personally I see no object in this. It can also be given by the mouth, but is more expensive than the hydrochloride, the bisulphate, sulphate and some of the other preparations.

Where there is anæmia and cachexia, quinine alone will not succeed; arsenic must then be employed in combination with one or other of the easily assimilable salts of iron. The results of such a combined treatment are excellent. A Bayer product, "Plasmochin" or "Plasmoquine," has recently been put on the market as a cure for malaria. At first used by itself, experience has shown that better results are obtained by combining it with quinine. The plasmoquine attacks the gametocytes specially, but is not so effective for the schizonts. The drug is put up in tablet form, each tablet containing plasmoquine 0.01 gramme (grain $\frac{1}{6}$) and quinine sulphate 0.125 gramme (grain 2). Of these two are given three times a day for five full courses of 6 days for M.T. and 7 days for B.T., an interval of 4 days taking place between each course. Toxic symptoms, such as a peculiar blue colour (?cyanosis), sickness, pain over the kidneys, etc., may be met with. The drug must then either be stopped and quinine substituted, or the dose reduced. In cases that have had much quinine and still get relapses, a course of plasmoquine Co. should be tried. Relapses may occur, however, even after the latter drug. The patient must also be warned against getting wet, bathing in the sea, taking cold baths at home, or drinking in excess. Any concurrent disease must be treated at the same time, otherwise success will not be achieved. Persons from the tropics not uncommonly suffer from syphilis and malaria. Dysentery and malaria is also a common combination. Some people say they cannot take quinine. If that be really so, then they

ought not to be allowed to go to the tropics. It is a good plan to give a test dose of 10 grains before the person leaves England.

BLACKWATER FEVER

Synonyms.—Hæmoglobinuric Fever; Melanuric Fever.

Definition.—An acute disease, associated in some way with malaria, characterised by high fever, jaundice and vomiting, and by the passage of hæmoglobin or methæmoglobin in the urine.

Ætiology.—The disease occurs in many parts of the tropics, especially in parts of Africa, Nyasaland, Uganda, East Africa, West Coast colonies, some parts of India, Duars, and Terai, in the Southern States of the U.S.A., Panama, British Guiana, Brazil, etc. Natives of the endemic areas seem to be immune, while colonists, natives from other parts of the world, and chance visitors are those attacked. Both sexes are equally liable, though more cases are seen in males, no doubt owing to the fact there are more males than females in the tropics as a whole. Children also suffer. The exact cause of the disease is unknown. There are two main views as to its causation.

- (1) It is a disease *sui generis*, the parasitic cause being as yet undiscovered.
- (2) It is in some way or other connected with malaria. Chills and depressing circumstances of any kind may precipitate the attack. All authorities are pretty well agreed that malaria, in some way or other, is connected with the production of the condition. Nearly, if not actually every case gives a history of many attacks of malaria, not necessarily severe, before the blackwater fever appears. The usual type of case is the patient who takes quinine when he has fever and then neglects to do so between attacks (irregular quinine taker). One interesting point in the geographical distribution of malaria and blackwater fever is that this does not completely coincide, there being, it is true, severe malaria where there is blackwater; but, on the other hand, there being plenty of malarial areas where there is either no blackwater fever at all, or only very rare cases (most of India, for example, the Federated Malay States, and other parts of the world). Again, if natives of India, where there is malaria but no blackwater fever—Sikhs, for example—go to Uganda they take the disease in a virulent form, and many of them die from it. It is still possible there is a specific parasite, which only acts in people who have suffered from malaria.

Quinine is not the cause, but it may, if given in large doses, precipitate an attack, and the name of quinine hæmoglobinuria has been given to such cases. It is better not to use this term, as quinine will not produce hæmoglobinuria except in those with a liability to it, e.g. persons living in, or who have lived in, blackwater countries. A cold bath or a chill in England will precipitate an attack of blackwater fever even though the patient has never suffered from the disease previously while abroad. The patient has brought his predisposition with him and is capable of developing the disease, though no longer living in its endemic haunts. There are many interesting points still requiring elucidation in the ætiology of the disease.

Pathology.—What actually causes the hæmolysis to take place is not known; there may be some abnormal instability in individuals attacked.

The liberated hæmoglobin is carried to the liver, which deals with as much of it as it can, the residue passing to the kidneys and being excreted by them, either as methæmoglobin or hæmoglobin, in the urine. The intense yellow colour of the patient is thus also explained.

The yellow colour is very noticeable and the body may appear blanched. If malaria has recently been present, the organs will show the pigmentation of that disease; in addition, however, the liver is enlarged and soft, the spleen also may be very big and the pulp almost diffuent. The kidneys are enlarged and congested, and the tubules blocked by hæmoglobin infarction. *Definite nephritis, though not usual, may also be present. There is nothing of importance in the brain.*

Symptoms.—A pre-blackwater fever stage has been described, but it is doubtful if this can really be differentiated from the ordinary malaria cachexia seen in bad malarial districts. The patient usually, though not always, thinks an ordinary attack of malaria is impending. Rigors may start the illness. The urine is now noticed to be black, the colour of dark port wine or porter, and this indicates the nature of the disease. There may be pain and aching in the loins with vomiting and hiccough. Great restlessness supervenes, the fever keeps high, the skin begins to show the characteristic yellow colour, and there is marked tenderness and pain in the epigastric region and over the liver. The vomiting may be persistent, preventing nourishment being given by the mouth, and greatly weakening and distressing the patient. This condition lasts for from *three to four days*, and then the urine begins to clear; in favourable cases the temperature now drops, the hæmoglobin completely disappears, the vomiting and other symptoms subside and convalescence is established. In all cases, however, careful watch must be kept for the appearance of the following additional symptoms: (1) Syncope; (2) Suppression of urine; (3) Hyperpyrexia; (4) Post-hæmoglobinuric fever; (5) General asthenia.

1. *Syncope.*—If the hæmolysis has been excessive, the signs and symptoms resemble those of ordinary hæmorrhage, namely, sighing respiration, weak flickering pulse and the other signs of shock. Syncope, especially if any attempts at movement be made, may quickly supervene.

2. *Suppression of urine.*—The urine may quickly diminish in quantity, become thick and tarry, and finally cease, the kidneys refusing to function further owing to blocking of the tubules with hæmoglobin. If this become absolute then a fatal termination of the disease is certain.

3. *Hyperpyrexia.*—The temperature may begin to rise rapidly, quickly reaching 107° F., 108° F. to 110° F. or higher, when death takes place.

4. *Post-hæmoglobinuric fever* occurs after the urine has cleared, and is difficult in many instances to explain.

5. In some cases, again, though the hæmoglobinuria has ceased and the other symptoms have subsided, the patient may not rally, but fall into an asthenic condition from which he cannot be roused, and death takes place. The effect of the hæmolysis on the malarial parasites, which are practically always present in all cases before the onset of the disease, is interesting. *This hæmolysis may result in the malarial infection being completely abolished, though this is not invariable. The parasites in the latter instance return, and cause further malarial relapses either with or without hæmoglobinuria.*

Complications and Sequelæ.—Permanent damage to the kidneys may

result, albumin persisting in the urine and interstitial changes developing in the organs.

Diagnosis.—This is usually easy—the history of residence abroad in English cases gives the clue. Other hæmoglobinurias have to be excluded, and for this the Autolytic Reaction will be found of use. This consists of cooling a tube of the patient's blood on ice for 5 minutes, and then incubating at 37° C. for an hour. In paroxysmal hæmoglobinuria intense hæmolysis results, whereas in real blackwater fever there is no change. Bile in the urine has been mistaken for hæmoglobinuria, but in cases of doubt the spectroscope will quickly decide the matter.

Prognosis.—This is always grave. No disease is so treacherous as blackwater fever, and until convalescence is well established the result is always uncertain. If the case can be admitted to hospital early, the chances of a successful termination will correspondingly increase.

Treatment.—Careful nursing is everything. The patient must be watched night and day, and must not be allowed to move or raise his head from the pillow. The bowels may be opened by calomel. The urine must be measured with great care and any diminution at once noted. If signs of suppression be threatening, intravenous, subcutaneous, or rectal saline, up to 1 pint, should at once be given, and hot packs should be applied to the loins. If the pulse be failing and the blood pressure very low, saline injections intravenously are indicated, or glucose or gum injections might be tried. Blood transfusion was recently used with success in a very severe case by the author, and the possibility of such a measure should be considered in all severe cases, especially in the type of case where the blood does not begin to improve and the patient passes into an asthenic state. Hyperpyrexia requires ice, and the usual remedies. Decapsulation of the kidney has been recommended for complete suppression. It would seem to be a somewhat desperate measure. Quinine should not be given, as it may increase the hæmolysis. For the vomiting, Hearsey has recommended a modification of Sternberg's yellow fever mixture—Bicarbonate of soda, grs. x, liq. hydrarg. perchlor. ℥xxx, every 2 hours for the first 24 hours, and then every 3 hours till the urine clears. This is said to stop the vomiting and to produce a free diuresis. Mercurial poisoning has followed its use, so care must be taken in its administration. Owing to the vomiting the patient may have to be fed per rectum. Easily assimilable foods should be given; as a stimulant, champagne is said to be of value. Careful return to ordinary diet should be insisted on during convalescence. For the post-hæmoglobinuric fever the bowels should be opened by some laxative, the condition sometimes resulting from constipation. If malaria return, it must be treated by small doses of quinine, 1 or 2 grains at a time, to begin with, cautiously increased by 1 grain per dose till 5 grains or more are reached; the patient should not return to the endemic area, as he is specially liable to further attacks.

LEISHMANIASIS

Leishmaniasis is a name applied to a group of diseases caused by parasites of the genus *Leishmania*. Some of these are general infections, others local. Of the first, we have kala-azar, due to the *L. donovani*, and infantile

or Mediterranean kala-azar, caused by the *L. infantum*, though this is now generally supposed to be the same species as the former, and if so the name *L. donovani* holds for both. Oriental sore, due to the *L. tropica*, and American dermal Leishmaniasis, to the *L. americana*, belong to the second group.

KALA-AZAR

Definition.—Kala-azar, or black fever, is a specific disease associated with enlargement of the spleen and liver, anæmia, and general emaciation, caused by a protozoal parasite, the Leishman-Donovan body, *L. donovani*.

Ætiology.—The disease has definite geographical limits, being commonest in India, Assam and the Mediterranean; in addition, it has been met with in China, Indo-China, Egypt, and in other parts of the world. Natives are perhaps more prone to the disease than Europeans, but this is due no doubt to their habits of life and not to any racial reasons. Children suffer as well as adults, especially from the Mediterranean form.

Leishmanial parasites are small oval- or oat-shaped bodies, 2 to 4 μ long by 1 to 2 μ broad, with two small chromatin bodies laterally placed and lying opposite each other. One of the bodies, the larger, macronucleus or trophonucleus, is round, while the other (centrosome, micronucleus or kinetonucleus) is rod-shaped, with one end usually pointing towards the former. They can be cultivated outside the body if grown on hæmoglobin agar medium (N.N.N. medium) at 22° C., when they elongate and pass into the flagellate stage. They now measure up to 24 μ in length, with the flagellum and centrosome at one end and the macronucleus in the middle (Herpetomonas type). It is supposed this flagellate represents an intermediate host stage in some insect, and Patton has found such changes in the blood in the stomachs of bugs that had sucked kala-azar bloods. Basile in Italy believes the dog flea, *Ctenocephalus canis*, is the spreading agent for Mediterranean kala-azar, the parasites being acquired from infected dogs. Quite recently Knowles, Napier and Smith have found that *Phlebotomus argentipes*, which corresponds in its distribution with kala-azar in India, becomes infected with leptomonas forms when fed on cases of the disease. It may possibly be the vector of the parasite. Recent work has tended still further to incriminate it.

Dogs suffer severely from the disease in the Mediterranean littoral, whereas in India (Madras) they seem to be free. This is interesting, as dogs can quite easily be infected experimentally with the Indian strain of parasite in England.

Pathology.—The parasites are distributed generally throughout the body, inhabiting the endothelial type of cell. In the spleen, they are also found in the large macrophages or splenic cells, in the bone marrow, in the myelocytes, and in large cells analogous to the macrophages of the spleen. They have been found also in the lungs, the testicles, and other viscera, and in the ulcers in the intestine and the lymphatic glands draining them (Manson and Low). In the peripheral blood they occur in the leucocytes, but are often so scanty as to require cultural methods to demonstrate their presence. They act as irritants, causing enlargement of the liver and spleen.

On autopsy, the spleen is firm to the touch, hard and fibrous, with the capsule and septa much thickened; the liver is also enlarged, and a fine form of cirrhosis is sometimes seen. The yellow bone marrow becomes converted into red, and is soft and disfluent. The skin sometimes shows papules or ulcers in which the *Leishmania* may be demonstrated, and recently some cases have shown a heavy parasitic infection in the lower layers of the skin, though unbroken and unaltered. The ulcers in the intestine are met with either in the small or large bowel; they are small and somewhat punched out, and the lymphatic glands draining the areas are enlarged.

Symptoms and Course.—In the epidemic form of the disease, as seen in Assam, Bentley states the cases start with fever of a remittent type which lasts from 2 to 4 weeks. During this time the spleen and liver enlarge. An interval of apyrexia succeeds, followed by a repetition of the fever. After some time a low form of fever sets in, accompanied by profuse drenching sweats, with pain in the limbs, anæmia and progressive emaciation. The skin becomes of an earthy colour; petechiæ, epistaxis and bleeding from the gums are common. The duration of the disease, in the days of Bentley's observations, was from a few months in acute, to 1 or 2 years in chronic cases. Ninety-six per cent. died, usually of some intercurrent disease such as dysentery, tubercle or asthenia. Besides these epidemic forms, Bentley described ordinary forms in natives; they were characterised by general weakness, debility, loss of flesh, fever perhaps at nights and enlargement of the spleen. Such cases showed no malarial parasites, but *Leishman-Donovan* bodies were found when the spleen was punctured.

In Europeans the symptoms closely resemble those seen in ordinary splenic anæmia. They may be classified as follows: (1) Irregular remittent or intermittent pyrexia, not necessarily high, the curve generally showing a double daily rise (double remittent type of Rogers). (2) Cachexia with deepening colour or pigmentation of the skin—whence the name black fever. (3) Anæmia and characteristic blood changes. (4) Rapid loss of weight. (5) Enlargement of the liver and spleen. (6) Sweating at night. (7) Hæmorrhages. (8) Diarrhœa—often of a dysenteric type.

The blood changes in kala-azar are those of an anæmia and leucopenia. The red cells usually fall to about 50 per cent. of the normal, but not much below. Poikilocytosis is not specially marked, a moderate amount only being present. Irregularity in size is also not extreme, but microcytes and megalocytes occur. Nucleated red corpuscles are not common—about one in every 500 leucocytes. They are of the normoblast type. Basophilia is rare. The hæmoglobin is proportionately diminished to the red corpuscles, e.g. about 50 per cent.

Striking changes are seen in the white cells, their number per cubic millimetre sinking to 2000 or under. This marked leucopenia should always arouse suspicions of the disease in any one who has resided abroad. Differentially, the large mononuclear cells are increased, but not to such an extent as in malaria; 8 to 12 per cent. is a fair average. In certain cases, parasites can readily be found in the leucocytes, but in others they are rare or apparently absent.

A typical blood count in kala-azar would read as follows: Reds, 2,500,000 (50 per cent.); Whites, 1200; Hb., 50 per cent.; differentially large mononuclears, 12 per cent.

The disease has been transmitted congenitally, a baby born in England to a kala-azar mother acquiring the disease (Low and Cooke).

Complications and Sequelæ.—In addition to hæmorrhages and ascites, dysenteric diarrhœa is common, depending upon the amount of ulceration in the gut. Real amœbic dysentery may also be superadded; and phthisis not infrequently carries off the patient. Congestion of the lungs and pneumonia occur. Cancrum oris is common amongst affected children in Calcutta. The ulcers in the bowel sometimes perforate, producing purulent peritonitis.

Diagnosis.—The *Leishmania donovani* must be demonstrated before one can finally say the case is one of kala-azar. Non-Leishmanial splenomegaly is also met with in the tropics. The liver or spleen should be punctured and the parasites searched for, or attempts may be made to cultivate them from the blood on N.N.N. medium (hæmoglobin agar). Napier's "Aldehyde test," which consists of adding one drop of 30 per cent. formaldehyde to 1 c.c. of clear serum from the patient's blood, may also be employed. If positive, the serum immediately becomes solid and opaque like the white of a hard-boiled egg. Other diseases give a modified positive reaction, however. A very marked leucopenia, in a person from a kala-azar area, should always make one suspicious.

Prognosis.—This used to be very bad, but since the introduction of intravenous antimony medication is now quite good and hopeful—especially if the case be treated early.

Treatment.—Bugs should certainly be destroyed wherever possible, and no one should sleep in houses where kala-azar patients reside or have recently resided, unless it be certain the houses are scrupulously clean and free from bugs. The destruction of old bug-infested coolie lines in Assam, and building of new ones, is said (Dodds Price) to have greatly diminished the disease in these parts.

Steps must also be taken to prevent, as far as possible, the bites of *Phlebotomus argentipes*.

In the Mediterranean areas, dogs should not be allowed into the houses; those known to be infected ought to be killed, and all means to prevent flea bites should be adopted.

There is only one drug that need be mentioned, and that is antimony in the form of antimonium tartaratum or tartar emetic (potassic-tartrate of antimony), or one of its other salts. It would seem to be a real specific, and its introduction into the treatment of kala-azar has robbed the disease of most of its terrors. The drug is given intravenously in a 2 per cent. solution, or simply dissolved in 10 c.c. of normal sterile saline or distilled water as required. It is then sterilised by boiling. The solution should be freshly prepared, and must not be allowed to stand. The introduction into the vein may be made with a syringe or by the gravity method, and care must be taken the solution is passed into the vein, as if it leak into the tissues sloughing occurs. It is usual to begin with a small dose of half a grain, increased by half a grain each time, until a maximum dose of 2½ grains is reached. The injections should be given every other day, or perhaps better, bi-weekly. The total quantity required will be somewhere between 40 and 60 grains in all.

Under the injections the temperature falls, the patient gains weight, and the symptoms of the disease gradually disappear. The cure seems to be

a permanent one. The general health should also be built up by suitable food and other coincident infections—malaria, syphilis, dysentery, helminthic infections, etc.—treated. Marmite may be given at the same time to increase the leucocytes. The sodium salt, antimony sodium tartrate, is preferred by some, and is said to be less toxic. Various other preparations of antimony have recently been put on the market, some of which are said to be as good, or even better, than tartar emetic. Of those one may mention Von Heyden 471 = meta-chlor-para-acetyl-amino-phenyl-stibiato of sodium. This is put up in ampoules of 0.1, 0.2 or 0.3 gramme, and can be given intravenously every second day; Oscal stibium, a preparation containing Sb_2S_3 in true colloidal suspension—strength, 1 in 2000, dose 1 c.c. intramuscularly twice weekly; or Stibamine glucoside (Neostam) twice weekly, dose 0.1 or 0.2 gramme intravenously; Urea stibamine, dose 0.1 or 0.2 gramme twice weekly; and Stibacetin.

ORIENTAL SORE

Synonyms.—Tropical Sore; Aleppo Sore; Bagdad Boil; Delhi Boil; Biskra Button; Bouton d'Orient; Date Boil, etc.

Definition.—An infective granuloma of the skin and subjacent tissues; the skin in some instances remaining intact, in others breaking down with the formation of chronic indolent ulceration.

Ætiology.—The condition is very common in parts of the East, notably in Bagdad, in Mesopotamia, in Lahore and Delhi in India, in Asia Minor, Arabia and Persia. It has also been noted in the Sudan and in Nigeria. It is due to a *Leishmania*, *L. tropica*. The parasite can be easily cultivated on N.N.N. medium; it is inoculable experimentally, and an insect, most probably a sandfly, is supposed to be its disseminator. *Phlebotomus papatasi* is now generally supposed to be the vector.

Pathology.—The lesion is that of an infective granuloma, granulation tissue with plasma cells, and large cells full of parasites. When the sore breaks the ordinary organisms of suppuration become implanted upon it, and the parasites may then be difficult to find. They can generally be recovered from the margins.

Symptoms.—The incubation period varies—it may be as long as 5 or 6 months. The sore starts as a small itching papule, which extends and gradually ulcerates the skin. The ulcer has fairly well-defined edges, and somewhat closely resembles a gumma. It is found on the exposed parts—hands, face, etc. Without treatment, the sore lasts a long time, even up to a year. They may be multiple.

Diagnosis.—This is made by finding the specific parasite. The best place to search for it is in the spreading margin of the sore. A hypodermic needle, or better, a fine glass tube should be inserted, and the juice sucked up may be inoculated into hæmoglobin tubes, smears being made at the same time for ordinary examination. The parasites may take some time to grow, and the cultures should be examined for several weeks before deciding they are negative.

Prognosis.—This is good, the sores eventually disappearing. The scars, however, if the lesion have been extensive, may be unsightly, especially on the face. As a rule, immunity follows healing of the sore.

Treatment.—Avoidance of bites from insects—a difficult procedure—is to

be advised. Many treatments have been tried: CO₂ snow, X-rays, radium, vaccines of killed cultures, methylene-blue, iodoform, salicylic acid, etc. Castellani recommends injections of oleum phosphoratum into the nodule and around it, in doses of 5 minims twice weekly. Antimony (tartar emetic) treatment is the best method to employ, the drug being administered intravenously or applied locally as a 2 per cent. ointment (Low). (See antimony treatment of kala-azar, p. 230.) In Bagdad, inoculation has been practised—somewhere on the limbs—to prevent the chance of a sore on the face with consequent disfiguration by scarring.

AMERICAN DERMAL LEISHMANIASIS

Synonyms.—Espundia; Uta; Pian Bois; Pian Cayenne; Forest Yaws; Bosch Yaws; Bubas Braziliانا.

Definition.—An infective granulomatous condition either occurring locally as unbroken tumours (blind nodules) or as ulcers, these often being followed by a generalised infection which attacks and finally destroys the buccal and nasal mucosa.

Ætiology.—It is found in South America, in Brazil, Venezuela, British and Dutch Guiana, Bolivia, Peru and Paraguay. The condition is due to the *L. americana*. The disease is specially frequent amongst wood-cutters and people living in the forests. Some wood-loving insect-tick or bug is supposed to be the transmitting agent.

Symptoms.—The incubation period is variable. The sore starts as a small papule or pimple, which gradually extends, and in many instances ulcerates the skin. Without treatment, the sores last a long time, but finally may heal. The arms are very often affected, and the margin of the ear is another favourite site. At a variable time after the primary sore, small ulcers may appear, either round the margins of the mouth or nose, and by extension of a serpiginous nature gradually destroy the parts.

Diagnosis.—Finding the parasites completes the diagnosis; they will be seen, if carefully looked for, in scrapings of the ulcerated areas, or may be grown in cultures. Syphilis, rodent ulcer and malignant disease closely resemble the destructive forms.

Prognosis.—Before antimony treatment was introduced this was hopeless, death taking place in the generalised infections by gradual exhaustion and sepsis. Now, even though the buccal ulceration has commenced, it can be cured.

Treatment.—This is similar to that adopted in oriental sore and kala-azar. In view of the serious nature of the secondary lesions a full course of 30 or 40 grains—in toto—of tartar emetic should be given when the original sore appears.

TRYPANOSOMIASIS

Definition.—Trypanosomiasis is a term used to designate the invasion of man and other animals by flagellate parasites of the genus *Trypanosoma*. Two distinct forms are known in man, the African and the South American. Similar parasites also cause serious diseases in animals, nagana and surra being the best-known examples.

AFRICAN TRYPANOSOMIASIS (HUMAN)

This form of the disease is endemic in parts of equatorial Africa, and is due to two varieties of trypanosomes. In the initial stages the infection is characterised by irregular remitting fever, increased pulse rate and respirations, œdemas and irregular erythematous rashes—in the later stages (sleeping sickness), by gradually increasing lethargy, mental and physical degeneration, progressive emaciation, tremors, other nervous phenomena and death.

Ætiology.—The disease is limited geographically to areas where the intermediate host, the tsetse fly, occurs. The equatorial belt of Africa includes nearly the whole distribution, the Congo, Uganda, East Africa, Rhodesia, Nyasaland, etc., being the areas chiefly affected. There is no race discrimination between the whites and the natives. It occurs in children, and in both sexes equally.

1. The Central African type is due to *Trypanosoma gambiense* carried by the *Glossina palpalis*, the Rhodesian and Nyasaland to the *T. rhodesiense* carried by *G. morsitans*.

Nagana is a disease of cattle and horses due to a trypanosome, *T. brucei*. This trypanosome is found in the blood of the wild game in certain districts, and the tsetse fly, *G. morsitans*, after biting such game becomes infected. The trypanosome has now to undergo a development in the fly, and after this has taken place, forms find their way into the salivary glands and so into other animals bitten. The infection does not seem to trouble the wild game specially, but when non-immune animals are taken into tsetse-fly belts they are bitten by infected flies and develop a virulent type of the infection of which they quickly die.

As regards the form of human trypanosomiasis due to *T. gambiense*, the reservoir of the infection would appear to be in game which lives near lakes and rivers (Speke's tragelaph—the sitatunga—the reed buck, bush buck, etc.), and the *G. palpalis* receives its infection from those animals and so passes it on to man. The disease is strictly limited to the areas where this special tsetse fly lives, namely, on the banks of rivers and lakes.

2. The Rhodesian type of infection (due to *T. rhodesiense*) is quite different, for here the fly that spreads it is the *G. morsitans*, a fly which lives in dry arid country often far away from water. The reservoir for the trypanosome is again the game of the area, and it is possible, as Bruce believes, that this variety is really the same as nagana, and that it is just the animal disease occurring in man. If Bruce's contention be correct, then the name of *T. rhodesiense* would have to give way to *T. brucei*.

As the clinical symptoms and pathological details are similar in the two varieties just described, they may be considered together.

Pathology.—There is little or no doubt the lesions produced are due to toxins excreted by the trypanosomes; the parasites may, however, also produce local damage by passing through the vessels into the tissues. There is little to note macroscopically. The brain often looks like ground glass and has a fairly characteristic appearance in most cases. Sometimes a definite purulent meningitis exists. Microscopically, the changes found are those of a chronic meningo-encephalitis and meningo-myelitis. The whole pia-arachnoid is infiltrated with mononuclear cells and a similar change

spreads along the septa, and affects, in varying degree, the perivascular spaces round the blood vessels. The cerebral fluid is in excess and finally contains trypanosomes. The pressure on the vessels by the proliferation of cells in the perivascular spaces accounts for the peculiar lethargy seen in life. Small-celled infiltration round the vessels, with trypanosomes lying in the surrounding tissues, is found in the viscera. The lymphatic glands are enlarged and congested, with a proliferation of lymphocytes.

Symptoms.—For convenience of classification the African form of human trypanosomiasis may be divided into—(1) The phase of trypanosomiasis fever. (2) The phase of sleeping sickness; the latter again being subdivided into—(a) A stage of indefinite symptoms with some degree of drowsiness and increasing languor; (b) the stage of drowsiness, marked lethargy, tremors and other definite phenomena; and (c) the terminal stage of emaciation, intense weakness, gradually increasing coma and death. These different phases pass insensibly into each other just in the same way as the phases of syphilis.

The disease may run an acute or chronic course.

1. TRYPANOSOMIASIS FEVER.—The incubation is a short one, as judged by experimental inoculations in animals—5 days or so. In several of the Rhodesian cases the infective bite was followed by cellulitis round the puncture wound. After the incubation period is over the following symptoms appear: (1) An irregular remittent or intermittent temperature. (2) An increase in the pulse rate to 100 or 120 or more. (3) An increase in the respiration rate to 20 or 30. (4) Irregular patches of a congested or erythematous character, often somewhat circinate in contour, the colour returning after pressure and distributed chiefly on the trunk. (5) Edema of the legs, or face, or both, varying in degree from a scarcely noticeable swelling to well-marked puffiness. (6) Adenitis.

The disease, if untreated, terminates in sleeping sickness or in some intercurrent infection.

2. SLEEPING SICKNESS.—(a) *First phase.*—This begins very insidiously, months or even years after the original trypanosome infection. The patient complains of indefinite pains in the chest; though previously quick and alert, he becomes dull and disinclined to work, with loss of weight, glandular enlargement, and there may be some slight tremor of the tongue. (b) *Second phase.*—The facial aspect gradually changes, the countenance becoming sad, apathetic and morose. The disinclination to do anything becomes more pronounced, and a tendency to doze or sleep constantly now becomes evident. The speech is mumbled and slow, the gait shuffling, tremors are marked—fine fibrillary ones in the tongue and arms—and glandular enlargement may be visible even at a distance. (c) *Third phase.*—All the symptoms become more pronounced, the patient takes to his bed, muscular weakness and wasting become very noticeable, the lethargy is much increased, saliva dribbles from the mouth, the skin may lose its lustre, papular eruptions and bed-sores are common, and epileptiform convulsions often occur. In young adults flexure-contractions of the limbs render the condition a miserable one. The drowsiness eventually passes into coma from which the patient cannot be roused, the temperature falls to subnormal, the body and extremities become cold and clammy, and death takes place. Anæmia in varying degrees is constant in the disease. The average number of red corpuscles is about 3,000,000 or under per c.mm. Just before death, there may be an abnormal

rise (over 6,000,000 per c.mm.), but more usually a gradual fall (under 2,000,000) takes place. The hæmoglobin is reduced proportionately, the blood showing all the characteristics of a secondary anæmia. The leucocytes are normal, or slightly diminished in number; certain cases show a well-marked terminal polymorpho-nuclear increase just before death. Differentially, the large mononuclears are increased—10 to 12 per cent. Trypanosomes are present in the blood, but may be very scanty and difficult to find.

Diagnosis.—All irregular fevers occurring in people who have been living in areas where sleeping sickness is endemic, especially if not influenced by quinine, should be viewed with suspicion. The pulse rate and respirations should be carefully studied and the skin examined for the circinate erythematous patches. Attention should also be given to any adenitis. Trypanosomes should be searched for in blood films, in the glandular juices and in the cerebro-spinal fluid. They should always be demonstrated before making a diagnosis and commencing treatment. The serum-formalin reaction, Napier's "aldehyde test" (*vide* p. 230) has lately been recommended for the diagnosis of trypanosomiasis. It is said to be positive, and to have some value.

Prognosis.—Since modern methods have been introduced this is more hopeful in the *gambiense* cases. Almost all, without exception, of the Rhodesian cases have died, as apparently this is a very much more virulent type.

Treatment.—Destruction of forest and bush round the edges of lakes and rivers will drive away the *G. palpalis*, and render the area safe. To deal with *G. morsitans* is quite a different matter, and is practically impossible. The destruction of game has been suggested; it is difficult to see how this could be done, and it is not altogether clear if such destruction would have the desired effect. We require to know more regarding the infections of the smaller mammals before attempting means of this sort. In passing through *palpalis* areas, gloves should be worn and a gauze net placed over the head. Shorts should not be allowed. When travelling in *morsitans* areas there is little chance of escape from being bitten, and then it becomes purely a matter of luck whether the bite is infectious or not. Recently two new drugs have been introduced into the treatment of the disease, namely Bayer, "205" and tryparsamide. The former is given in 1 gramme doses weekly until a total of 10 grammes in all has been taken. The drug is very efficacious in early cases, but apparently is not so good in the late stages of the disease when the central nervous system is involved. Unfortunately it produces an albuminuria and during the administration the patient should be kept in bed warm, and on a milk diet. In most cases this symptom is eventually recovered from. Failures have recently been noted with "205." In many instances, however, the drug was not administered in a proper manner, the dosage being too low.

Tryparsamide is given to begin with in 1 gramme doses, these being increased to 2 or even 3 gramme doses weekly, until a total of 20 or 30 grammes in all has been taken. Eye symptoms—affections of the optic nerve—may follow the administration. Dr. Louise Pearce speaks well of the drug and has used it extensively in the later stages of the disease, in natives in the Congo. Previous to the introduction of these new drugs treatment consisted of atoxyl injections, 2½ to 3 grs., into the buttocks, twice weekly, these being continued for 6 months to a year. At the same time long courses of tartar emetic were given intravenously, beginning with half-grain doses, bi-weekly,

and gradually increasing to $2\frac{1}{2}$ grs. for a maximum single dose. As much as 60 grs. *in toto* were given for a course. After a rest a second course was undertaken, and so on, for 2 or even 3 years. Whichever method is adopted the patient's general health must be built up in every way, and all other infections, if present, be eliminated.

SOUTH AMERICAN TRYPANOSOMIASIS (HUMAN)

Synonyms.—Chagas' Disease; Coreotrypanosis.

Definition.—A trypanosome disease, with symptoms very similar to those of insufficiency of the glands with internal secretions.

Ætiology.—The disease has been recorded in Brazil, but possibly has a wider distribution, which necessarily will be limited by that of the intermediate host. Children suffer from the disease as well as adults. The disease is due to the *T. cruzi*, man becoming infected by the bite of the *Lam. megistus*, also known as *Conorhinus megistus*, which apparently can transmit the infection in the larval, nymphal and imaginal stages. The flagellates are found in the peripheral blood after infection, only for a comparatively short time (2 weeks only in many cases). They then pass into the internal organs and assume a Leishmanial form, such forms producing pathological lesions in the organs infested, where the parasites divide, and from time to time trypanosome forms are produced which may find their way back into the peripheral blood. When the larvæ of *L. megistus* absorb infected blood, the trypanosomes quickly take on the crithidial form, multiply actively, and then become trypanosomes again, which are inoculable into vertebrates.

The carrier of *T. cruzi* in Venezuela is the *Rodnius prolixus*.

Pathology.—Vianna gives the following as the post-mortem appearances. **Polyorrhomenitis**, with serous effusions of a yellow colour; constant swelling of the lymphatic glands of the abdominal cavity, mediastinum, neck, axilla and groins; fatty degeneration of the liver, swelling and softening of the spleen; sclerosis, hypertrophy and cyst formation, often with calcification, of the thyroid gland; frequently myocarditis and changes in the suprarenal capsules. The Leishmanial forms of the parasite are found specially in the heart muscle, voluntary muscles, brain, thyroid gland, suprarenals, ovaries and testicles. The central nervous system shows cell destruction and areas of inflammation, the meninges very marked inflammatory changes, and many of the small arteries exhibit slight perivascular changes. The pathological conditions found are those of a meningo-encephalo-myelitis.

Symptoms.—Chagas divides the disease into acute and chronic forms.

Acute.—These acute forms are very common in young children, even in the first months of life. They are subdivided into—(a) the encephalo-meningitic form, the mortality in which is very high owing to the brain involvement, and (b) where there are no nervous symptoms, the prognosis being more favourable, the disease usually passing into one of the chronic forms. The main feature of all the forms would appear to be an insufficiency of the glands with internal secretions, hypothyroidism predominating, though suprarenal inadequacy is also common.

The temperature keeps up as long as the parasites exist in the peripheral blood, the thyroid gland is enlarged, the subcutaneous tissues show an acute

mucous infiltration, the lymphatic glands are swollen, hepatomegaly is present, and the spleen moderately enlarged. If the brain be involved the symptoms of encephalo-meningitis are present as well.

Chronic.—Five clinical groups are comprised under this heading—

- (1) Pseudo-myxœdematous; (2) Myxœdematous; (3) Cardiac; (4) Nervous; (5) Chronic, with subacute manifestations.

In the first group, the thyroid gland is enlarged, the face is puffy, and the skin a peculiar colour like dull bronze. The lymphatic glands are enlarged, and there is a high degree of cardiac insufficiency; hypothyroidism is pronounced. Convulsions are frequent.

In the second group, the picture is one of typical myxœdema—arrest of growth, solid œdema, parchment skin, etc.

In the third group, there are various disturbances of the heart rhythm, extra systoles, heart block, and other irregularities, due, no doubt, to the presence of the parasites in the myocardium.

In the fourth group, paralysis, aphasia and idiocy are common. Owing to the occurrence of the parasites in multiple foci in the brain, different motor symptoms are met with—spastic phenomena, diplegia, athetosis and flexure contractions. In children, the mental intelligence is always below par, all transitions between complete idiocy and a simple cretinoid state existing.

In the fifth group, the fresh manifestations may either be due to fresh infection or to lighting up of some of the existing foci. The results acquired from a study of such cases has led Chagas to believe the trypanosome in its later developments in the tissues of man becomes almost exclusively a connective-tissue parasite.

Diagnosis.—In the early stages this can be made by finding the trypanosomes in the blood. In the later stages, when the parasites have disappeared, it is not so easy. Puncture of some of the voluntary muscles might reveal the Leishmanial form of the parasite, which is diagnostic.

Prognosis.—This is not good.

Treatment.—The destruction of *Lamus*-infested houses must come first in the prophylaxis of the disease. All such insects should be destroyed where possible—by fumigation or by other methods. So far no cure is known for the disease; but antimony injections should certainly be given a trial. As such injections act so well in Leishmanial infections, it is reasonable to suppose they might also do so in this disease.

AMOEBIĆ DYSENTERY

Definition.—An invasion of the colon of man by the *Entamœba histolytica*.

Ætiology.—This dysentery is found throughout the tropics, sub-tropics, and even in temperate regions. Both sexes and all ages are liable. The *E. histolytica* gains access to the body in its cystic form by the mouth in drinking water, or on contaminated vegetables. This passes the stomach safely, after which the wall of the cyst is dissolved by the pancreatic juice, and the young amœbæ contained in the cyst escape, pass down the intestine and locate themselves in the mucous membrane of the colon, where they form adult amœbæ (vegetative forms) which live on the tissues; the amœbæ again form cysts, which escape in the stools, and so disseminate the infection.

Pathology.—The *amœbæ* histolyse the tissues with which they come in contact, and finding their way into the submucosa, form ulcers in the large bowel, which tend to extend longitudinally, the openings in the mucous membrane in consequence being narrower than the floor of the ulcer (bottle-necked ulcer). The edges of the ulcers are raised and hardened, with marked undermining. There may only be a few ulcers, or practically the whole of the mucous membrane from cæcum to rectum may be involved. Without treatment, the ulceration tends to become chronic, and though healing in some places, breaks out in others. The *amœbæ* are seen lying in large numbers throughout the necrosed and dead tissues. When an ulcer heals a flat pigmented scar is left.

Symptoms.—The condition may begin as a diarrhœa (*amœbic diarrhœa*), but later, as a rule, blood and mucus appear in the stools, the latter often consisting of nothing but pure mucus and blood, in which *amœbæ* are easily demonstrated. Great pain, tenesmus, griping and purging, as many as 20 stools being passed per day, are concomitant. Even without specific treatment, the tendency for *amœbic dysentery* is to improve temporarily, but relapses are frequent, and very characteristic of the disease.

The *amœbæ* may be carried from the intestine and lodge in the liver (see article *Amœbic Hepatitis* and *Hepatic Abscess*, page 629), lungs, or brain (secondary *amœbiasis*). In the liver their presence gives rise to hepatitis, and if this be neglected, to abscess formation. The signs of an abscess in the liver are an irregular fever, often rigors, sweating at nights, pain in the right side and in the right shoulder, leucocytosis, with an enlarged and painful liver. If untreated, a chronic cachexia, with anæmia, supervenes, and emaciation may become extreme. In the brain the symptoms are similar to those of abscesses from other causes.

Complications and Sequelæ.—Abscess formation is the most serious complication of *amœbic dysentery*. When in the liver the abscess may burst into the lung and be coughed up, or it may burst into the pleura, the pericardium, stomach or large bowel. An ulcer of the bowel may perforate, or may cause adhesions with subsequent obstruction to the lumen.

Course.—Once the acute signs of dysentery abate, the vegetative forms of the parasite usually disappear, their place being taken by the cystic stage. Abscesses behind the colon are also met with. The patient becomes a carrier, liable, however, to frequent relapses with acute exacerbations from time to time.

Diagnosis.—This is made by finding the characteristic parasite in the stool, *E. histolytica*—living forms or its cysts. The latter generally have 4 nuclei with a chromatoid body, and measure on an average 10 to 14 μ in diameter. They may be made to appear in increased numbers in the stools by the administration of biliary extracts, and before declaring a patient clear this procedure should be tried. Sometimes they are extremely scarce, many examinations, even up to ten or more, being required to demonstrate them. The cerebral *amœbic abscesses* are impossible to diagnose from ordinary brain collections of pus.

Prognosis.—With modern methods of treatment this is good, a large proportion of cases being curable. There are, however, a small percentage which resist all forms of treatment (chronic resisters). The prognosis in liver abscess varies; it must always be considered a serious condition.

Cerebral amoebic abscesses are always fatal.

Treatment.—This is carried out by means of emetine, either by the mouth or needle; it is more efficacious given by the mouth, and more cases can be completely cured by this method; it should be administered as emetine bismuth iodide grs. iij in a hard gelatine capsule every night for 12 nights. By injection, 1 grain of emetine hydrochloride is given every evening for 12 consecutive nights.

If relapse occur after one course, a second course of double the dosage must be tried, namely, E.B.I. grs. iij, every night for 24 nights if the patient can stand it. Another plan is to combine the two methods, giving an injection in the morning and a capsule of E.B.I. grs. iij, at night. This large dosage must be carefully watched, as the heart often becomes affected and the patient feels very depressed and low (emetine poisoning). One has often to stop the treatment after 8 or 10 of these double doses have been given on account of this. In addition, the patient must be kept in bed and dieted with great care, albumin water, raisin tea and milk to begin with, and after convalescence white meat diet, the staple of which should be milk. No alcohol must be allowed, and great care should be taken to avoid over exertion and chills. Another method of treatment—not so drastic as the above—is that by emetine periodide (E.P.I.). This does not produce sickness and is given in 2-grain doses, three times a day for 10 days, *e.g.* 60 grs., or 51 in all. Willmore has had good results with this, even in cases which have failed to respond to emetine bismuth iodide. He recommends giving with each dose of the emetine periodide a 5-grain tablet of *fel bovinum*.

In emetine-resistant cases, *stovarsol*, first recommended by French observers, may be given. Though not apparently a true specific, it nevertheless improves some of the cases. It is administered by mouth, a 4-grain tablet being given once or twice a day for 10 days, then one tablet on alternate days, then one twice a week for several weeks. *Yatren*, a German preparation, has also been used. It is given by the mouth, in the form of a pill or a capsule, and at the same time the rectum is irrigated with a solution of it, 6 to 8 injections being given. It does good in some cases. The diet in these chronic cases must also be of the simplest nature. Abscess formation requires surgical intervention. Aspiration is the best method of treatment, this often resulting in cure after one evacuation. It prevents the secondary infection of the cavity with pyogenic germs, a contingency so often met with after the "open" or "trocar and canula" methods.

For BACILLARY DYSENTERY, see p. 85.

G. CARMICHAEL LOW.

E. INFECTIOUS DISEASES OF DOUBTFUL OR UNKNOWN ETIOLOGY

MEASLES

Synonym.—*Morbilli*.

Definition.—A specific infectious fever, characterised by catarrh of the respiratory passages, the presence of Koplik's spots on the mucous membrane

of the cheeks, a distinctive papular eruption on the skin and a special liability to pulmonary complications.

Ætiology.—Measles is of universal geographical distribution. Both sexes are equally liable to attack. It is extremely infectious, and there is little evidence that natural immunity ever occurs. When introduced among unprotected communities it spreads with appalling rapidity to persons of all ages, and causes many deaths. More than half the attacks of measles occur in the first 5 years of life, but infants under 6 months rarely take the disease. Seven-eighths of all cases occur in children under 10. Between the ages of 20 and 30 there is a slight increase in its incidence. After 40 years it is rare. When measles occurs in a pregnant woman abortion or premature delivery often results, and the infant may also exhibit the rash, usually in the same stage as the mother (*Congenital Measles*). Malnutrition, rickets, bronchopneumonia, whooping-cough and tuberculosis are adverse factors. Recent infection with diphtheria or scarlet fever predisposes to a severe attack. The disease is always endemic in large cities, and cases are particularly numerous in December, January and February, again increasing somewhat in May and June. Epidemics recur every two or three years, and every tenth year an especial incidence is said to be noticeable.

The virus resides in the secretions of the respiratory tract and direct infection is the rule, a very intimate contact not being essential. Infectivity may be present as long as 4 days before the appearance of the rash, and then rapidly declines. Only on rare occasions do intermediaries convey the infection, and rooms and fomites do not retain it for more than a short period. There is no evidence incriminating water, milk or other articles of food.

Pathology.—The causal agent has not been identified. A small diplococcus, which forms green colonies on blood-agar, isolated by Ruth Tunnicliff, is suspect. The disease has been reproduced in man and monkeys by inoculation with blood, bronchial secretions or tears. The eruption is an inflammatory process in the dermis, more superficially seated than that of scarlet fever. Koplik's spots are minute epithelial degenerations on the crowns of the papillæ of the buccal mucous membrane. The most striking visceral change in fatal cases is broncho-pneumonia; interstitial emphysema and areas of collapse may also be present, sometimes secondary pleurisy or empyema. Pulmonary fibrosis and saccular bronchiectasis may be sequels of an attack. Secondary infections with various organisms are common. Catarrhal or ulcerative laryngitis may be found. The bronchial glands are inflamed and swollen; the lymphoid aggregations of the small intestine may be very conspicuous. Tuberculous lesions of glands, lungs and serous membranes are not uncommon in fatal cases.

Symptoms.—The rash appears on the fourteenth day of infection, sometimes a day earlier or a day later. This interval is more constant than that which elapses between infection and the first catarrhal symptoms. Reckoning to the onset of fever and catarrh 9 or 10 days usually pass. In some cases the incubation period is slightly febrile, but generally it is silent. A polynuclear leucocytosis is characteristic of this stage. Slight enlargement of the cervical, inguinal, axillary and other glands may precede the eruption. A better recognised prodromal symptom, and one of very great value, is the appearance of Koplik's spots on the buccal mucosa; these may precede the rash by 2 or 3, sometimes by 5 days. Prodromal rashes are not un-

common; a precocious macular eruption is the commonest, but a punctate scarlatiniform erythema is the most important, since it simulates scarlet fever. It is apt to appear on the second day of invasion. An urticarial rash may also occur.

Invasion.—This is characterised by catarrh of the upper respiratory tract, fever, and the outbreak in the mouth of Koplik's spots. It culminates in the appearance of the skin eruption. Sneezing, a dry irritating cough, watery eyes and conjunctival injection are the early catarrhal signs. There is complaint of chilliness, and the temperature may reach 103° F. by the end of the first day. Photophobia and sharp diarrhoea may occur. Vomiting, marked sore throat, epistaxis, convulsion or rigor are rare. Even in the early stage of invasion slight blotchiness of the skin about the mouth and nose may be evident. The cutaneous rash usually appears on the fourth day, and a deceptive remission of symptoms and fall of temperature sometimes occur just before its appearance. In some instances laryngeal symptoms are very marked during the invasive stage, and give rise to an unfounded suspicion of diphtheria.

Koplik's spots are of great importance in the early diagnosis, since they are recognisable some 72 hours before the rash. They are minute superficial specks of a bluish-white tinge, and often show a tendency to aggregate into small clusters. Their common site is on the inner aspects of the cheeks, opposite the line of apposition of the molar teeth; but they may be more widely scattered over the buccal mucous membrane, on the inner surfaces of the lips, and even, it is said, on the conjunctivae. They must not be confused with minute yellow nodules in the mucosa, which are buccal glands, or with specks of milk curd, shallow ulcers or thrush. Sometimes they are surrounded by a bright red areola. In addition, the mucous membrane of the mouth becomes congested and dusky, and a decided blotchy enanthema may precede the cutaneous rash.

Period of eruption.—With the near approach of the rash the symptoms become aggravated. The temperature (Fig. 2) rises sharply, it may be to 104° or 105° F. The hurried respiration and slight cyanosis may suggest broncho-pneumonia. Diarrhoea may persist, and sometimes urinary irritation with frequency of micturition is noticeable. The nasal and conjunctival dis-

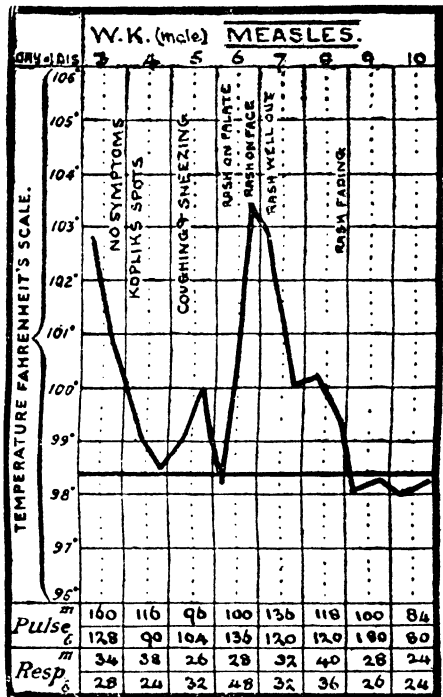

FIG. 2.—Measles. Showing the remission in invasion stage and the abrupt termination.

charges become less serous and more purulent. The eruption makes its first appearance about the brow, behind and below the ears, and in the circumoral region. Rarely, it appears first on other parts, such as the buttocks, thighs or wrists. It spreads rapidly, sometimes after a short hesitation, over the face, neck, trunk and extremities, and is usually fully out on the fifth or sixth day of the attack. Small brownish macules are the first elements, but they soon become papular, and show a tendency to fuse into small groups with irregular sinuous or crescentic outlines. Profuse eruptions may become quite confluent on the face, neck, back and extensor aspects of the limbs. Petechial hæmorrhages in the rash are not uncommon. The skin is usually moist, and exhales a peculiar musty smell. Rarely, it is hot and dry. Itching or burning sensations may accompany the rash. The eruption fades in the order of its appearance, and usually disappears in the course of two or three days; but brownish staining may persist for some time, particularly on the back. Exposure or bathing may intensify it. A fine branny desquamation speedily follows. At its first appearance, the rash may fail for a time to spread; retrocession is also sometimes observed. A badly developed and retarded rash is characteristic of some severe attacks, and in asphyxial states the rash may be quite cyanotic. As the rash develops, the temperature continues to rise, reaching its maximum with the climax of the attack in from 24 to 48 hours. When the rash begins to fade, the temperature falls more or less abruptly by a crisis which is rather prolonged. The pulse-rate is increased in proportion to the fever, but the respiration is disproportionately rapid. The catarrhal symptoms also reach their greatest intensity at the height of the eruption. The edges of the eyelids are sticky, the skin about the nostrils may be excoriated, the mouth is parched, and thirst is pronounced. Headache, slight delirium, insomnia and a feeling of intense wretchedness are characteristic of this period. The throat may be sore, and the glands at the angle of the jaw tender. The tongue at first is heavily coated, but before long red papillæ are evident, and when peeling is complete a clean, red papillated tongue, very like that of scarlet fever, may often be seen. With the crisis rapid amelioration of all symptoms should occur; but slight cough and hoarseness may persist for a few days.

The blood now shows a leucopenia with a high percentage of large lymphocytes. All complications induce a polynuclear leucocytosis.

The urine presents the ordinary febrile characters. Transitory albuminuria may occur. Ehrlich's diazo-reaction is nearly always present, and is most marked when the temperature begins to fall. An acetone reaction is obtained in most cases.

VARIETIES.—Attacks may be mild or severe. Some of the mildest attacks are aberrant, the rash failing to appear, and only Koplik's spots giving a clue to the disease. Severe attacks are classified as toxic, pulmonary and hæmorrhagic. The *toxic type* includes those cases formerly termed *ataxic* or *adynamic*, in which the patient may succumb during the eruptive period without evident complication. Ill-defined rashes, high fever, muscular tremor, delirium, dyspnoea and circulatory failure are characteristic features. In the *pulmonary type* the infection falls with especial stress upon the lungs. The temperature is high, the respirations rapid and hissing, and the condition suggestive of slow asphyxia. Consolidation of the lungs cannot be detected,

but rhonchi are present everywhere, accompanied by fine crepitations. A stuporose condition may precede death or terminal convulsions may arise. The true hæmorrhagic type of measles is rare, but undoubtedly does occur. The patient may bleed from the different mucous membranes with hæmorrhages into the skin and subcutaneous tissues. Recovery takes place in some instances. Hæmorrhage into the rash has not the same grave significance as the hæmorrhages described above.

Complications.—These are numerous, but those involving the respiratory tract are the most important and most serious.

Laryngitis may accompany the onset, develop during the eruption, or appear early in convalescence. Arising in the invasive stage it may simulate laryngeal diphtheria, and is often responsible for the introduction of measles into diphtheria wards. Laryngitis is more common during the eruptive period, and may persist for some days—it may be complicated by laryngeal ulceration, sometimes by oedema of the glottis; but necrosis of the laryngeal cartilages and abscess formation are rare. Severe laryngitis developing during convalescence should always arouse suspicion of diphtheria.

Bronchitis is often present during the eruptive stage, but broncho-pneumonia is a much more serious complication, and is a common cause of death. Its incidence is favoured by overcrowding, and contact with other similar cases. It is attributed to secondary pneumococcal or streptococcal infection; but when occurring quite early in the infection it is by some regarded as due to measles itself. This early broncho-pneumonia is associated with a high temperature and considerable toxæmia. It is suffocative in type, and the lung signs are rather those of capillary bronchitis than of consolidation. During the eruptive stage, broncho-pneumonia should be suspected if the temperature fails to fall with subsidence of the rash, and the pulse remain quick and respiration rapid. In some cases it is possible to detect areas of consolidation by the local development of fine crackling crepitus, which is both inspiratory and expiratory in rhythm. Faint tubular breathing may occasionally be heard, but definite dull patches are the exception, and are only found when the consolidated areas become confluent. Broncho-pneumonia may clear up in a week or ten days, but often persists for weeks, or relapses. The temperature chart may show remarkable daily remissions and exacerbations which may lead to suspicions of tuberculosis. The mortality is serious, since one-third or one-half of the children attacked are said to die. Feeble infants succumb more rapidly than older children, and in those who recover convalescence is protracted. True lobar pneumonia is uncommon. Massive collapse of the lower lobe of a lung has been described; its onset is sudden with intense dyspnoea, cyanosis and cardiac failure. It is distinguished from pneumonia by the feebleness of the breath sounds, upward displacement of the diaphragm, and dislocation of the heart towards the affected side. Effusions into the pleura have been noticed in some epidemics, and empyema may follow. Fibrosis of the lung and bronchiectasis may originate in the broncho-pneumonia of measles.

Pericarditis is very rare. Endocarditis sometimes develops; it may be associated with chorea. Arthritis with rheumatic pains is sometimes pronounced.

Blepharitis and phlyctenular ulcers of the cornea are common sequela.

In cachectic children intense conjunctivitis may arise and lead to ulceration and even perforation of the cornea with destruction of the eye.

Stomatitis of catarrhal type is common. Ulcerative and gangrenous forms are occasional complications. The gangrenous form (noma) may attack the lips, cheeks, vulva or other parts. A discoloured patch appears on the mucous membrane and quickly ulcerates, extending both in depth and breadth. A zone of inflammatory induration surrounds the lesion, and a foetid odour is given off. Noma is terribly destructive both to soft parts and bone, and is very fatal. It occurs in debilitated and feeble children, and is attributed to secondary infection. Vincent's spirilla and fusiform bacilli are often present. It is said to be sometimes due to the Klebs-Loeffler bacillus. Suppurative otitis is more common in children than in adults, and is held responsible for much chronic ear disease.

Cutaneous eruptions of eczematous, impetiginous or pustular type are common. Sometimes they are widespread, and very resistant to treatment.

Enlargement and suppuration of the cervical glands, colitis and ascites are rarer complications.

As regards the nervous system, convulsions at onset are not so serious as those occurring later. Hemiplegia, aphasia, coma or mental defect are rare, and are attributed to encephalitis. Myelitis, sometimes of the ascending form, has been known to occur; also symptoms suggestive of disseminate sclerosis. Sometimes the cranial nerves are attacked. Paralysis of extra-ocular muscles, papilloedema and optic atrophy have all been encountered. The peroneal type of muscular atrophy sometimes follows measles.

Measles especially favours the development of tuberculosis hitherto latent in the bronchial glands or lung. It may also light up tubercle in other glands in the joints or in the spine. Caseous broncho-pneumonia, miliary tuberculosis of the lungs, or general tuberculosis with meningitis may follow measles immediately or occur after a quiescent period. Measles often occurs in close association with other infectious diseases, particularly whooping-cough, diphtheria and scarlet fever.

Relapse in measles is rare. Second attacks, although uncommon, undoubtedly occur, and some unfortunate individuals never appear to acquire any lasting immunity. Fourth, and even sixth, attacks are known.

Diagnosis.—In the prodromal stage, measles may be mistaken for ordinary naso-pharyngeal catarrh. If laryngitis be pronounced, and the child croupy, diphtheria may be simulated. Mastoid operations and operations on the tonsils sometimes are performed precipitately before the true nature of the infection is recognised. Febrile symptoms and loss of weight during the incubation stage may be erroneously attributed to tuberculous infection. The prodromal scarlatiniform rash may lead to confusion with scarlet fever. These errors may be avoided by bearing in mind the possibility of measles, inquiring for possible exposure to infection, and particularly by a careful search for Koplik's spots, and shottiness of the posterior cervical glands. The pre-eruptive fall of temperature and recession of the catarrhal symptoms before the appearance of the rash should be borne in mind, and not lead to premature relaxation of precautionary isolation. In the eruptive stage, the fevers with which measles may be confused are rubella, small-pox, and perhaps typhus.

Rubella is distinguished by the trivial nature of its prodromal symptoms

—the rash on the face being often its first sign; the slightness or absence of catarrh and cough; the insignificant fever; the absence of Koplik's spots; and the presence of tender enlargement of the mastoid and occipital glands. The rash of rubella is smaller, pinker, and more discrete; but a scarlatiniform stage may supervene. The patient never feels so ill as in ordinary measles.

Small-pox may be heralded by a prodromal rash of morbilliform character, which may have a similar distribution to that of measles, save perhaps on the face. Catarrh, stomatitis and Koplik's spots, however, are absent, and the onset is more abrupt than that of measles, and more likely to be signalled by such symptoms as backache, acute shivering, vomiting and prostration.

Measles may, on the other hand, be mistaken for the early eruptive stage of small-pox, for in both an illness for a few days may precede the appearance of a papular rash on the face and upper parts of the body. Catarrh, Koplik's spots and distribution of the rash about the ears, forehead and margins of the hairy scalp are in favour of measles. The temperature, too, continues to until the maximum efflorescence, whilst that of small-pox falls with the appearance of the rash. As the rash develops, the shottiness of the small-pox papules and the peculiarities of their distribution become apparent.

Typhus fever may be simulated by measles when the rash of the latter is receding and dusky, and lung complications are present; but the rash of typhus rarely invades the face, which is always affected in measles. Koplik's spots do not occur in typhus, nor is respiratory catarrh present in its early stages. Typhus is also distinguished by the subcuticular mottling, and the tendency to the appearance of petechial hemorrhages in the rash. The Weil-Felix reaction also is valuable.

Septic rashes in scarlet fever are often morbilliform; but their distribution does not conform to that of the measles rash. Serum rashes, food rashes, and drug eruptions may assume a measly character; but these rashes often prove to be polymorphic when the whole body is examined, as it should be, and, besides, other signs of measles are wanting.

The macular syphilide is distinguished by the absence of respiratory catarrh and Koplik's spots. History of exposure to infection, a chancre and the accompanying throat symptoms afford a clue. The Wassermann test should be employed.

Prognosis.—In different epidemics the death-rate may vary from 1 or 2 to over 50 per cent. Measles is most fatal to infants and young children, 70 per cent. of the mortality occurring in children under 3 years of age. After the fourth year the death-rate is low. Rickets, tuberculosis, congenital syphilis, malnutrition and chronic bowel complaints are unfavourable factors, and the disease is more fatal among the poor. In the cold season of the year the tendency to respiratory complications is more marked. When the infection occurs in conjunction with whooping-cough or chronic lung disease the mortality is high. Diphtheria is an especially fatal complication. Considerable toxæmia with high fever, cyanosis, muscular tremor and diarrhœa point to a severe attack. Laryngitis, capillary bronchitis and bronchopneumonia are serious. Cerebral symptoms, such as prolonged stupor or convulsions, are of bad augury. Remarkable recovery has been noticed in some cases of ascending myelitis.

Treatment.—*Prophylactic.*—Measles is chiefly disseminated by schools.

The difficulty in controlling outbreaks of measles arises from the fact that it is extremely infectious, and the infectivity is present in virulent form for 3 or 4 days before the rash appears. Notification and school closure have been tried with poor results. The best method is to exclude those in a class, who have not had measles previously, from school for a period covering the ninth to the fourteenth day after the occurrence of the first case.

As regards the home, when measles occurs those who have had the disease need not be excluded from school—save from infant classes; but those presumably susceptible should be excluded for over 14 days from exposure to infection.

Serum prophylaxis.—Intramuscular injection of the blood serum of healthy convalescents from measles into susceptible contacts produces a *passive* immunity, which lasts about a month. Injection during the first 5 or 6 days of the incubation period prevents measles if the dose is adequate. Injection after the sixth and before the ninth day will modify the severity of attack, and allow the development of an *active* immunity which is lasting.

Five c.c. is an average dose for a child; more is needed for adults or if the serum is injected late. In children under 3 years of age it is better to prevent the attack altogether. The most potent serum is obtained from the sixth to the ninth day after defervescence. The donor must be free from *syphilis*, *malaria* and *tuberculosis*, and must not be incubating any other infectious disease.

If measles follows the subcutaneous injection of immune serum the rash fails to erupt at the site of injection; this is the *Debré phenomenon*.

Systematic taking of temperatures and examination for Koplik's spots and catarrh facilitate early detection of the disease, when patients are under close observation. The wilful exposure of children to the contagion of measles is unjustifiable, as the nature of the resulting attack can never be predicted.

Fourteen days' quarantine is sufficient from the date at which exposure to infection ceased. Convalescent patients in the absence of complications are quite free from infectivity at the end of a fortnight from the appearance of the rash.

General.—Essential points are isolation and provision of ample fresh air without draughts. The patient must be confined to bed during the febrile, and also during the prodromal stage, if this be recognised in time. The sick-room should be kept at a temperature of 60° to 65° F., and ventilation effected by means of open windows; an open fire is also an advantage. The photophobia calls for the interposition of a screen between bed and window, and the avoidance of much light. Clothing should be light and consist of a flannel or woollen nightdress; this is sufficient to prevent chill, allows the respiratory muscles full play, and encourages the evaporation of perspiration. Strict attention should be paid to cleansing the mouth and teeth, and the regulation of the bowels. During the febrile stage the diet should be restricted to milk, diluted if necessary with barley water. Tea may be allowed, and lemonade or barley water given to assuage the thirst.

Twice a day during the febrile period the patient should be washed with tepid water; but should the attack assume a toxæmic form, accompanied by high fever and delirium, cold sponging or the use of the cold pack is advisable, watching carefully for any signs of collapse. Amidopyrin has also been

recommended. The hot mustard bath is useful for children when pyrexia is accompanied by such indications of circulatory failure as feeble pulse, cyanosis and cold extremities. Should convulsions ensue, the administration of chloral and bromide, or paraldehyde, by mouth or rectum, and the use of oxygen and of hot baths are valuable.

Laryngitis in the early stage is relieved by the steam tent and the use of a simple expectorant mixture, to which a sedative may be added. The croupy symptoms usually subside without necessitating tracheotomy or intubation. The possibility of the presence of diphtheria renders a bacteriological examination desirable.

Laryngitis which persists after the eruption may be alleviated by the inhalation of tincture of benzoin or lysol in the strength of 1 drachm to the pint of boiling water. The accompanying cough is relieved by a simple linctus, or one containing $\frac{1}{2}$ grain of morphine or other sedative. Late laryngitis is often diphtheritic, and needs antitoxin. Bronchitis and broncho-pneumonia call for prompt treatment. A jacket of Gamgee tissue should be applied to the chest. If the cough be dry, hard and irritating, steam often relieves. An expectorant mixture containing ipecacuanha and a small quantity of iodide of potassium is useful. Prolonged poulticing should be avoided; but sometimes a single mustard and linseed poultice gives great relief. As soon as the cough becomes looser, the steam tent should be discarded and free ventilation arranged. If possible, it is well to separate cases with broncho-pneumonia from others, as the condition is believed to be itself infectious. Treatment of the broncho-pneumonia of measles in the open air, where circumstances and weather permit, gives excellent results. Oxygen is valuable where there is much respiratory distress and cyanosis; it may be bubbled through rectified spirit, the container being immersed in hot water. Cardiac dilatation is an indication for the application of leeches. Frequent small meals are preferable to overloading the stomach.

Conjunctivitis should be met by frequent bathing of the eyes with boric lotion and the application of a little dilute nitrate of mercury ointment to the lids. In the more severe cases, drops of silver nitrate solution, 2 grains to the ounce, should be instilled night and morning, or a 2 per cent. solution of protargol used. Should the cornea ulcerate, atropine drops should be employed and ung. flav. dil. applied. Eye bandages are undesirable.

Stomatitis usually subsides quickly; the mouth should be cleansed with boroglyceride or a lotion containing chlorate of potash (10 grains to 1 ounce). The supervision of noma calls for surgical interference in the way of cauterisation or free excision. In an uncomplicated case of measles the patient may be allowed up 2 or 3 days after the temperature subsides. Supervision should be exercised during the convalescence of severe cases, and the possibility of later tuberculosis borne in mind. Ear discharges call for skilled treatment, as they may become chronic.

RUBELLA

Synonyms.—German Measles, R \ddot{o} theln.

Rubella is quite distinct from ordinary measles and from scarlet fever. It protects only against itself. Amongst the exanthemata it is characterised

by its long incubation period, its short invasive stage, its benign course and its seasonal prevalence.

Ætiology.—The infectivity is less than that of measles and of short duration. Like measles it is infectious for a day or two before the eruption appears. Infection is facilitated by close contact and there is no evidence that the disease is spread by fomites. Infection through an intermediary cannot be considered proved.

Rubella is prevalent in the first half of the year. Cases increase from January to a maximum in May and June. After that an abrupt fall ensues. A series of local outbreaks usually occurs, determined by the aggregation of a number of unprotected young adults. A more or less pronounced epidemic wave occurs every third or fourth year. The maximum incidence is at a later age period than that of measles, but even the youngest infants have been known to take the disease. Its frequency much diminishes after the age of 30. Sex is without influence.

Symptoms.—The incubation period, although variously stated to be from 7 to 22 days, is usually 17 or 18 days.

Premonitory symptoms are mild or altogether absent, but a short catarrhal stage usually occurs, the rash making its appearance within 24 hours. Rarely a longer prodromal period of ill-defined illness occurs before the eruption. The characteristic adenitis of the mastoid, occipital and cervical glands can, more often than not, be detected for a day or two, exceptionally even a week or longer, before the appearance of the rash.

The rash is often dimorphic. Papular and morbilliform in its beginnings, it frequently becomes scarlatiniform in its second stage. Discrete spots first appear on the face or neck; they invade the circum-oral region and may be found behind the ears and sometimes on the scalp. Sometimes they are first found on the wrists, chest, shoulders, or even on the legs. The spots are very slightly salient and when well developed are typically papular. They are smaller than the papules of measles, pale pink in colour, and tend to cluster in small groups. The rash quickly extends to the trunk and limbs and in most cases as quickly fades. On the second day the face is no longer spotty but appears diffusely erythematous. Sometimes the outbreak of the eruption is halting in its progress. The scarlatiniform stage is not developed in all attacks; it is due to the fusion of the morbilliform elements, and is generally best marked on the trunk, especially so on the back. It becomes most apparent on the second day of the eruption. The rash rarely lasts more than 72 hours and hardly stains the skin, thus contrasting with measles.

The mucous membrane of the mouth is not inflamed, and Koplik's spots never occur. The tonsils may be slightly swollen and reddened, sometimes a follicular exudate is present. Some degree of pharyngeal catarrh is evident, and the tongue may be lightly coated. A fine vesiculation and congestion of the soft palate is often seen. The conjunctivæ are pink and the eyes slightly suffused. Photophobia is rare. Fever is slight, even when the rash is intense. Often there is no fever at all. The pulse and respiration rates are only increased in proportion to the febrile disturbance.

A tender adenitis is very distinctive. The mastoid and occipital glands may rapidly attain the size of small peas; the posterior cervical glands are also enlarged, frequently too those in the axillæ and groins. The enlarged

glands are firm, tender and discrete; suppuration never occurs. As a rule resolution takes place rapidly when the rash subsides. The urine presents no special characteristics.

Convalescence is remarkably speedy. Slight furfuraceous desquamation may occur.

Complications.—Complications and sequelæ are for all practical purposes non-existent. When they do occur they are trivial and take the form of mild recurrent sore throat, slight laryngitis, slight bronchial catarrh, rheumatic pains of a mild type, or transient albuminuria. Otitis is very rare.

On occasions, epidemics of rubella of more severe type, approximating in symptoms and sequelæ much more closely to measles, have been described.

Diagnosis.—The disease has a similarity to measles and scarlet fever, especially when the latter occurs in a mild form. In addition, the rash of rubella must be distinguished from toxic and drug rashes, from the eruption of secondary syphilis and from certain skin diseases.

Measles is differentiated by the following points. The incubation period is shorter, being 14 days from exposure to the appearance of the rash; cough and catarrhal symptoms are marked, the mucous membrane of the mouth is inflamed and Koplik's spots are present. The rash is darker, more persistent, and stains. There is no late scarlatiniform stage. Fever is more pronounced, and the mastoid and occipital glands are not especially enlarged. Pulmonary complications are much more likely to occur.

Rubella is often mistaken for scarlet fever. Distinctive points in favour of the latter are: the short incubation period; the occurrence of such initial symptoms as vomiting, marked faucial inflammation, shivering or severe headache. The fever is high at onset and the pulse disproportionately rapid. The circumoral region is free from rash and by the fourth day the tongue has peeled. The occurrence of such sequelæ as arthritis, cervical adenitis and nephritis, also typical pinhole or lamellar desquamation, will clinch the diagnosis. Even in the scarlatiniform stage of rubella, discrete measly elements may generally be detected about the edges of the rash on the forearms, wrists, legs and ankles.

Toxic, enema and drug rashes may bear a resemblance to the rash of rubella, but as a rule these rashes are very irregular in their distribution and polymorphic in character. The characteristic glandular enlargement and slight catarrh of rubella are absent.

Of skin diseases, erythema scarlatiniforme and pityriasis rosea are sometimes mistaken for rubella. The first named bears a greater resemblance to scarlet fever; unlike rubella, it avoids the face, does not give rise to swelling of the mastoid and occipital glands, and shows a great tendency to recur.

Pityriasis rosea, itself possibly an infective fever, is distinguished by the presence of a herald patch which precedes the general eruption, and the fact that it usually appears first on the upper part of the trunk. The rash often shows commingled macular and ringed lesions. The patches are slightly scaly and are decidedly larger and more persistent than the papules of rubella. There is no catarrh and no conspicuous glandular enlargement about the head. The patches desquamate in a characteristic manner from their centres towards the margins.

Secondary syphilides bear a superficial resemblance to the rash of rubella, but are distinguished by the presence of a primary sore, the characteristic

throat and the conspicuous increase in size, and shottiness of the glands in the vicinity of the chancre. The Wassermann reaction is of value.

Prognosis.—Recovery is the rule; second attacks are known, but not common, and relapse is very rare.

Treatment.—*Prophylactic.*—As the incubation period is long a quarantine of 3 weeks is necessary for contacts, or they may be isolated from the tenth to the twenty-first day from exposure to infection. Early warning of the imminence of attack may be gained by carefully watching the mastoid and occipital glands.

General.—The patient should be isolated and kept in bed until all symptoms have subsided. In 7 days all infectivity has ceased, provided there is no persistence of faucial, nasal, respiratory or other symptoms.

SCARLET FEVER

Synonym.—Scarlatina.

Definition.—An acute specific fever of sudden onset characterised by faucial inflammation, a punctate erythema of the skin, and a tongue at first furred but later raw with prominent red papillæ. Desquamation follows, and inflammatory sequelæ may occur involving especially the ears, cervical glands and kidneys.

Ætiology.—Scarlet fever is a disease of temperate climes and seldom gains a foothold in tropical or subtropical countries. It is endemic in large cities and populous centres, tending to flare up every few years in local epidemic form owing to the accumulation of susceptible material. Its general epidemic prevalence, however, is irregular, and no definite periodicity has been recognised. In the United Kingdom it is prevalent in the latter part of the summer and reaches its maximum at the end of the autumn; a fall in the number of cases then occurs, the period of least prevalence being the spring. Of late years, although the prevalence has not appreciably declined, the mortality has fallen and the type of case become less severe. Severity, however, still varies greatly in different years and in different localities.

The case mortality of scarlet fever (proportion of deaths to attacks) is not more than 1 or 2 per cent. It is greatest in the first year of life and diminishes with age. Females are more liable to infection than males, but attacks in males are rather more likely to terminate fatally.

Of predisposing causes, childhood and the absence of acquired immunity are the most important. Infants under one year of age seldom contract the disease. The maximum incidence occurs during the fifth and sixth years of life, a period slightly later than is the case with such diseases as whooping-cough and measles. Adults are not exempt, but scarlet fever is rare in the aged. As a rule, one attack protects permanently, but second attacks do undoubtedly occur. Multiple recurrences should probably be referred to some other cause than scarlet fever.

Poverty, by entailing shortage of food, overcrowding, and defective isolation, facilitates the spread of the disease and augments its death-rate.

The virus resides in the mucous secretions of the nose and throat and in the secondary suppurative lesions. The disease is infectious from its commencement, but the exact duration of infectivity cannot be determined for

any given case. Six weeks' isolation is generally sufficient if by that time the mucous membranes be healthy and the skin free from sores. Many authorities reduce this period to 4 weeks for mild and uncomplicated attacks. Late desquamation is not regarded as dangerous, and the infectivity of urine which remains albuminous has never been proved. The infectivity of scarlet fever is not nearly so great as that of measles, varicella or small-pox.

In most cases infection is derived directly from a person suffering with, or recently recovered from, the disease, but transmission by infected fomites or infected milk may also occur. It is an important fact that discharges from the nose, throat, mouth and ear may remain infectious for many weeks, and pre-existing purulent discharges also become infectious when scarlet fever is contracted. The occurrence of catarrhal infection of the nose or throat in a scarlet fever convalescent may lead to a recrudescence of infectivity.

Intermediary carriers have on occasions spread the disease without themselves showing signs of infection. On rare occasions, too, convalescents, although apparently healthy, have for months remained capable of transmitting the fever. The infectivity of carriers appears to be intermittent, and the receptivity of those exposed is increased by debilitating circumstances or acute disease of which diphtheria may be cited as an example. Attendants on scarlet fever cases, although long immune, may finally contract the disease.

Infected milk may be responsible for localised and, sometimes, for more widespread outbreaks of the fever. In most instances the milk has been infected from a human source, but possible derivation of infection from cows with ulcerated udders and teats is suggested by the well-known Hendon outbreak. Scarlet fever is not known to be transmitted by water or by sewage. Cases of wound infection are not numerous, but puerperal scarlet fever is well recognised.

Pathology.—Klein, in 1887, isolated a streptococcus from the teats and udders of cows at Hendon, and considered it the causal agent in a milk-borne epidemic of scarlet fever. It has been customary, however, to regard the streptococci found in the throats and tissues of scarlatinal cases as secondary invaders, it being impossible to grow these organisms from the blood of patients suffering from the fever in its toxic, and presumably uncomplicated form.

Drs. George and Gladys Dick, of Chicago, have now produced evidence that scarlet fever is a local infection of the throat by a hemolytic streptococcus and attribute the general symptoms of the disease to toxins absorbed from the local focus. They have infected patients with scarlet fever by swabbing the fauces with a pure culture of their organism and have elaborated a test analogous to the Schick test in diphtheria. This is the Dick test. It is made by the intradermic injection of 0.1 c.c. of a 1 in 1000 dilution of toxic broth filtrate in saline solution. Boiled filtrate is used as a control. An erythema at the point of injection, maximal in 24 hours, indicates susceptibility to scarlet fever. The same types of reaction occur as in the Schick test (*q.v.*). During the first few days of scarlet fever a positive result may be expected. A certain number of convalescents remain positive to the test, but the majority become negative.

Susceptible persons can be immunised by subcutaneous injection of

minute but increasing doses of scarlatinal toxin at intervals of 4 to 7 days. For adults four or five injections are required, commencing with 500 "skin test" units and ending with a dose of 10,000 units. Immunity develops more slowly than in the case of diphtheria, and its duration is unknown. If the Dick test proves positive 6 months after, a further injection is recommended in the case of those nursing scarlet fever.

By immunising horses, an antitoxic serum is produced, which is said to bring about a rapid amelioration of the acute symptoms of scarlet fever.

Schultz and Charlton pointed out that intradermic injection of 1 c.c. of the serum from a patient convalescent from scarlet fever will, in a few hours, cause a local blanching of the rash of the fever. This is known as the blanching test. W. Mair suggests that the test is due to antitoxic immunity in the donor, which will account for its occasional failure, and also the fact that the serum of some donors not known to have had scarlet fever, will give the reaction. The antitoxin prepared from the Dicks' scarlatinal streptococcus possesses the same blanching property, and is now used for the test.

The post-mortem appearances in scarlet fever are not distinctive. The rash, unless hamorrhagic, disappears after death. Such gross changes as are found in the fauces, cervical glands, lungs, kidneys and liver, together with moderate enlargement of the spleen and lymphoid structures, merely indicate an acute infective process. In severely toxic cases, early decomposition with much post-mortem staining of the tissues, fluidity of the blood and subserous ecchymoses, indicate the intensity but not the nature of the infection. In cases surviving longer, inflammations of the lungs, serous sacs, endocardium, pericardium and joints may possibly be present, and desquamation may be recognised. Scarlatinal nephritis is described as being essentially glomerular in type, but other parts of the kidney are also involved.

Symptoms.—The incubation period is short, the period which elapses between infection and the development of the first symptoms being from 2 to 4 days, with an average of 72 hours.

Invasion is abrupt, the cardinal symptoms being vomiting, headache and sore throat. In some severe cases vomiting may be so urgent as to suggest irritant poisoning, especially if accompanied by diarrhoea; in mild cases vomiting may be absent. Rigor is uncommon, convulsions occasionally occur in children. Cough and catarrhal symptoms are decidedly rare, but a mild conjunctival injection is not unknown. The skin is hot and dry, the cheeks flushed, and the eyes bright. The limbs ache, the appetite is in abeyance, and the tongue rapidly becomes coated with white fur, through which the papillæ project as red points. Slight nocturnal delirium is common. The temperature rises rapidly, and even on the first day may reach 103° or 104° F. An undue acceleration of the pulse is usually a marked characteristic, rates of 160 or more are common in young children, and rates of 120 to 140 in adults.

Very mild cases often occur, and in these the symptoms of invasion may be absent, the rash being the first indication of the disease.

Uniform injection of the tonsils, fauces, and uvula is present in the early stages of the disease. Later, the injection becomes more vivid, the tonsils are swollen, and a distinct follicular exudate often appears; inflammatory oedema of the fauces soon makes its appearance in severe cases, and may be

accompanied by free mucous secretion. The tonsils may become covered by a thin necrotic film, or a more or less coherent exudate may form which may encroach on the faucial pillars and base of the uvula, and closely simulate the membranous exudate of diphtheria. In the more severe forms of scarlet fever, the tonsillar and faucial inflammation is very intense, and both ulceration and sloughing occasionally occur; thick muco-pus trickles down from the naso-pharynx, and acrid discharge blocks the nostrils and excoriates the upper lip. The respiratory obstruction is especially severe if adenoids are present. In severe cases, inhalation broncho-pneumonia is a decided danger.

A punctate injection may often be seen on the soft palate and adjacent part of the roof of the mouth even before the appearance of rash on the skin, and is of diagnostic value. The eruption usually appears within 24 hours of the invasion, but may be delayed. It appears first on the upper part of the chest, the root of the neck and the upper arms as a finely punctate erythema; sometimes it is first seen in the axillæ. It quickly spreads to the trunk and limbs, reaching the legs last. The cheeks are merely flushed, and the existence of an area of circum-oral pallor is a well-known and striking feature. The thick skin of the palms and soles is also in most instances free from the distinctive rash. The eruption often shows a symmetrical intensification in certain regions, such as the lower abdomen and groins, the inner aspects of the thighs, the axillæ, the back, and the points and flexures of the elbows and knees.

Of the two elements of the rash, one is minutely punctate, the other erythematous. It is the former which gives it its distinctive character. On coarse skin the puncta are particularly large and may be palpable. When the erythematous element is intense the skin may actually appear œdematous and the puncta be quite obscured. In such cases, on subsidence of the rash, yellow staining may be apparent. In addition to punctation and erythema, minute petechiæ or small linear hæmorrhages are sometimes seen in the flexures of the groins, elbows, wrists and knees. These remain when the rash has faded, and together with coarse injected papules on the outer sides of the arms and legs afford valuable evidence when the rash has gone. The rash on the buttocks and extremities may assume a slightly blotchy papular appearance, and so bear a distant resemblance to that of measles. Minute sudamina sometimes accompany the rash, giving rise to the variety known as *scarlatina miliaris*. Itching is not common.

The rash may be quite transitory or may last a week or even longer. Generally speaking, it is more pronounced in severe attacks but sometimes attacks which are quite mild show rashes of considerable intensity and persistence. A dusky, blotchy, morbilliform eruption, generally limited to the convexity of the knees and elbows, but sometimes more widespread, may supervene in grave cases. It is known as the *septic rash*.

At the time of the initial faucial inflammation, the glands at the angles of the lower jaw are swollen and tender. During the eruptive period a moderate enlargement of the axillary and inguinal glands, sometimes of the posterior cervical glands as well, is often to be detected. The spleen is rarely to be felt. At times the glandular swelling leads to confusion with rubella, but the glands do not attain the size or show the marked tenderness characteristic of the latter disease.

P. J. F.

In an average case a rapid rise of temperature (Fig. 3) marks the invasion, but the maximum may not be attained until the full development of the rash on the third or fourth evening, when readings of 103°, 104° or even 105° F. may be registered. Slight morning remissions occur. The fall is by lysis, reaching the normal by the fifth or sixth day of the disease. Termination by crisis is unusual. In bad cases of a septic type, the fever is prolonged, with increasing daily oscillations as septicæmic symptoms become prominent. In the malignant type of the disease, the fever is higher from the first and shows less remission, but occasionally is sub-normal throughout. A protracted remittent fever may occur in scarlet fever without local symptoms or complications to account for it; this variety is sometimes known as the "typhoid type."

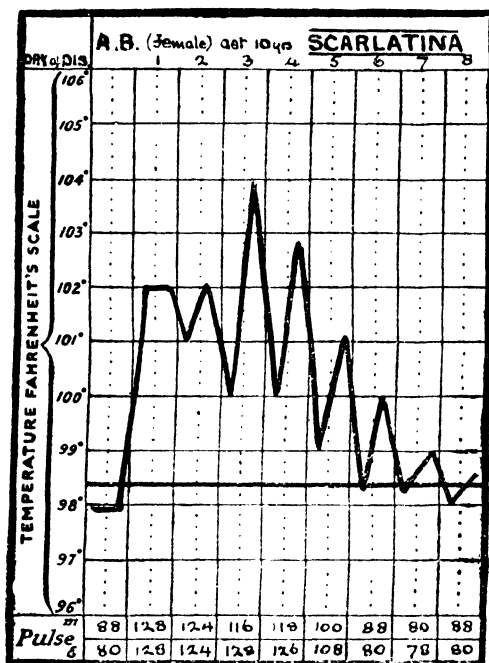

FIG. 3.—Simple scarlet fever. Showing abrupt onset and rapid lysis.

Abrupt rises of temperature during the convalescent period may signalise the onset of such complications as adenitis, otitis, nephritis, endocarditis, empyema, or a metastatic abscess. Sometimes such pyrexial attacks occur without ascertainable cause, but a thorough examination of the patient is always necessary. Very mild cases of scarlet fever without obvious febrile disturbance certainly exist.

Desquamation is a well-known characteristic, but the degree to which it occurs is very variable. The tongue peels in patches or strips, and by the fourth day is raw with prominent papillæ (*raspberry tongue*). The flushed cheeks begin to shed a fine powder

during the febrile period. Fine peeling of the lobules of the ears, of the margins of the lips, and of the skin at the root of the neck, possibly also above the pubes, next makes its appearance. By the end of the first week, peeling is generally well marked on the neck, chest, inner sides of the arms and possibly on the trunk. Within a fortnight it may be seen on the hands and possibly on the feet. It may not be complete on the latter until over 6 weeks from the onset of the fever. Patial re-desquamation often occurs on the soles and is not infectious. The characteristic of the desquamation is the pinhole or ringed form in which it commences, the horny layers of the skin being shed first over the summits of the papillæ, forming apertures which enlarge centrifugally and fuse with their neighbours. Where the skin

is thick, as on the hands and feet, it tends to separate in larger flakes, or may even be thrown off in the form of incomplete casts. A rather characteristic form of peeling is sometimes seen on the finger-tips when separation begins, as a split parallel to the free edge of the nail.

In severe cases considerable loss of hair may accompany or follow desquamation, but is temporary only, at all events in the younger patients. Furrows may also appear across the nails and take several weeks to reach the free edge.

Although desquamation typically proceeds as described above, there are cases of true scarlet fever where it is insignificant. It is unsafe to pronounce definitely against scarlet fever until 3 weeks have elapsed. In doubtful cases the hands and feet should be watched with care. A dry powdery appearance of the palms and soles sometimes is the sole indication of peeling. During desquamation the skin may appear harsh, dry, cracked or even eczematous.

A polymorphonuclear leucocytosis makes its appearance shortly after infection and reaches a maximum with the full development of the rash. It persists a variable time, and eosinophilia is generally marked during convalescence. Fluidity and slow coagulation of the blood are indications of severity, but apart from this blood examination has little prognostic value. Döhle has described certain bodies seen in the polymorphonuclear leucocytes when stained by Leishman's method as being characteristic. They appear in the acute stage as more or less definite blue spots in the cytoplasm of the cells. They are, however, not exclusively found in scarlet fever.

Varieties.—These are: (a) Simple or Benign; (b) Septic or Anginous; and (c) Toxic or Malignant. Surgical or Wound Scarlet fever and scarlet fever occurring during pregnancy or the puerperium, also have special characteristics.

Simple scarlet fever is characterised by an onset of moderate severity in which the initial vomiting is not repeated and sometimes is absent. The faucial inflammation is slight, and the temperature, which may reach 102° F., has almost reached its acme in 24 hours; generally the climax is reached by the third day and amelioration of symptoms is then rapid. The urine may be normal throughout, or a trace of albumin may accompany the febrile disturbance. By the third or fourth day the tongue, at first slightly coated, has peeled, and slight powdering may be evident on the cheeks. Convalescence is rapid.

The *Septic or Anginous* variety comprises most of the severe and fatal cases. It is characterised by intense faucial inflammation and a tendency to the development of septicæmic manifestations. Repeated vomiting, sharp diarrhoea and prostration may signalise the onset. The faucial inflammation is either severe from the first or unexpectedly becomes so after a lapse of 2 or 3 days. The tonsils are much swollen and a patchy or coherent membranous exudate may form. Rapid and destructive ulceration of the tonsils, soft palate and its pillars sometimes occurs. The mucous membrane of the mouth may be excoriated and bleed at the slightest touch. The pharynx, and even the upper aperture of the larynx, may become involved in the inflammation, although, as a rule, implication of the latter is more suggestive of diphtheria than of scarlet fever. The discharges from the throat excoriate the angles of the mouth and a purulent acrid rhinorrhœa irritates

the nares and upper lip. Deglutition is painful, respiration is obstructed, and the patient often sleepless, restless and later delirious. The cervical lymph glands become swollen and tender, and peri-adenitis or extensive sloughy cellulitis of the neck may ensue. This sometimes gives rise to fatal hæmorrhage by eroding large veins or even an artery. Cyanosis and coldness of the extremities and cardiac dilatation are common. The rash is generally intense, dusky and blotchy. The temperature often reaches 104° or 105° F. in the early stages of the disease, and pyrexia may persist long beyond the ordinary period and, changing its type, assume a remittent or intermittent septicæmic form.

Death may occur in the first week; more often life is prolonged into the second week, by which time circulatory failure becomes pronounced; hypostatic congestion of the lungs or spreading broncho-pneumonia occurs. Otitis, arthritis, suppurations of the serous sacs, endocarditis, or nephritis may appear as complications.

Many patients show septic symptoms of a much milder type and make good recoveries. In grave cases which recover, improvement is very gradual and usually sets in towards the end of the second week, but may be later.

Toxic or Malignant Scarlet fever is characterised by a toxæmic condition out of all proportion to the degree of inflammatory reaction in the throat. Such cases are marked by high fever, cerebral disturbance, profound prostration and heart failure. The rash is often petechial, but in the most severe attacks the patient may die before it has time to appear, and the real nature of the disease only be revealed by the supervention of scarlet fever in contacts. The throat may be intensely injected, but the œdema, ulceration and thick purulent secretion which characterise the septic variety may be absent altogether. Sometimes convulsions precede death, but mostly delirium merges into coma. Rarely, however, the patient dies of cardiac failure with vomiting, prostration and extreme pallor, but with clear intellect, suggestive of the type of death seen in some cases of diphtheria.

Sufferers from the malignant type of scarlet fever mostly succumb within a week of the onset, sometimes within 24 hours. But, as in the septic form, cases of the toxic or malignant type are not now so common or characterised by such extreme malignancy as was formerly the case.

Rarely scarlet fever assumes a hæmorrhagic form, with bleeding into the skin and from the mucous membranes. It is possible, however, that some of the cases formerly so described were really hæmorrhagic small-pox with prodromal rashes of scarlatiniform character.

Surgical Scarlet fever may be a sequel of operations, wounds, or burns and scalds. It is more often seen after operations on the nose and throat than elsewhere. The incubation period is short, often less than 3 days, and the rash may make its first appearance round the wound. Faucial inflammation in such cases is often slight. Although the type of fever as a rule is mild, the infected wounds show a great tendency to suppurate. If the infection start from a wound or abrasion on a limb, injected lymphatic vessels are often evident which show a characteristic punctate rash. The corresponding lymph glands are enlarged and tender. When the fever follows burns or scalds the incubation period is also short and the accompanying angina may be slight. Cases of surgical and of burn scarlet fever are not highly infectious.

They are often left in general wards with impunity, but at the same time there is no doubt that occasionally they spread the infection.

Scarlet fever may arise in the pregnant woman. In early pregnancy it is rare, and is said not to lead to abortion; but occurring later it is very prone to produce abortion or premature delivery. When the infection occurs either immediately before or immediately after labour, it is apt to assume a grave form with a very high mortality from septicæmia; but there is no doubt mild attacks may occur even at this period.

Anomalous forms of scarlet fever may occur in which one or more of the cardinal symptoms are lacking. In some only sore throat is recognised (*Scarlatina sine eruptione*), and yet the patient may transmit the typical disease; in others the rash, although present, is so ephemeral or atypical that its true nature escapes recognition; in yet others, the rash is the most pronounced feature, both fever and sore throat being insignificant. In cases where the rash is very scanty or insignificant, desquamation may not be at all marked.

Complications.—These are numerous and important. They may provisionally be divided into two groups; those which arise locally in connection with the faucial and pharyngeal inflammation, and those of a general or more remote character. To the first group, in order of frequency belong *otitis*, *cervical adenitis*, *rinitis*, *secondary tonsillitis* and *stomatitis*, and *aspiration broncho-pneumonia*. The second group includes *rheumatism*, *albuminuria*, *nephritis*, *endocarditis*, *pericarditis*, *pleurisy* and *empyema*.

In severe cases complications show a great tendency to occur in combination rather than singly.

Otitis.—This is met with in from 10 to 15 per cent. of the cases, and is an inflammation of the whole mucous tract of the middle ear. Its greatest frequency is in childhood, and its incidence is favoured by the presence of adenoid tissue in the naso-pharynx. It is more common in severe cases, and may show itself by the end of the first week of the fever or later. *Raché* with an injected and bulging tympanic membrane are the signs to be expected, but sometimes a free discharge of muco-pus or pus and blood from the ear is the earliest indication. Unexplained pyrexia not due to fresh faucial or glandular extension or to one of the distant complications should always lead to a careful examination of the ears. Perforation, which usually is rapid, generally occurs in the upper part of the tympanic membrane. A very marked degree of deafness may occur, but fortunately is transient in most cases. Pain and tenderness with slight cedema of the mastoid appear in some instances, and may be accompanied by restlessness, vomiting and fluctuating temperature. The intensity of these mastoid symptoms may vary from day to day. In children the mastoid air cells are very superficial, and pus easily makes its way beneath the covering periosteum.

Sometimes the labyrinth becomes implicated either by extension through its fenestræ or primarily. In such cases deafness, vomiting, vertigo and nystagmus may occur. Labyrinthine deafness may be permanent.

Such intracranial complications as meningitis, extradural abscess, lateral sinus thrombosis, cerebellar or temporo-aphenoidal abscesses, belong to the more chronic forms of ear disease, but occasionally they arise during the acute stage of scarlet fever and need, more than ever, prompt recognition and surgical treatment. Persistence of mastoid tenderness with some local

headache and slight fever may be the only signs of inflammatory mischief invading the dura in the vicinity of the lateral sinus.

In most instances scarlatinal otitis subsides in a few weeks and the perforation of the membrane closes.

Adenitis.—A rapid and considerable swelling of the upper cervical lymph glands may occur during the convalescent stage of the fever. The swollen glands are usually those behind the angle of the mandible or higher up under the insertion of the sterno-mastoid muscle. The adenitis generally supervenes during the second, third or fourth week of the disease. It is marked by local tenderness and a sharp accession of fever. In favourable cases the temperature becomes normal in a day or two and the glandular swelling rapidly subsides, but suppuration may ensue.

Secondary tonsillitis should suggest the possibility of diphtheritic infection. Peritonsillar abscess may also occur. Ulcerative stomatitis with much fœtor of breath and sometimes even sloughing of soft tissues and necrosis of bone are also looked upon as a secondary infection. Vincent's organism and diphtheria bacilli should be sought for in such cases.

Rhinitis.—Acrid or purulent rhinorrhœa is characteristic of septic attacks. A simple rhinorrhœa which occurs in the later stages of the fever is often responsible for the transmission of infection by patients supposed to be cured. True diphtheria bacilli are more frequently found in the nasal than in the ear discharges of those suffering from scarlet fever.

Nephritis.—Slight albuminuria occurring during the eruptive stage of scarlet fever is transitory and of no great importance, but during the third week, sometimes a little earlier, sometimes a little later, a characteristic nephritis may supervene. It is to be expected in a little over 3 per cent. of the cases, and is more common in severe than in mild attacks. Chill, damp and exposure favour its incidence. The onset may be insidious or fulminant. In the insidious cases albuminuria, at first slight, and even intermittent, is the first sign. In the fulminant cases, headache, vomiting, pyrexia and even rigor may mark the onset. The urine becomes heavily loaded with albumin, casts and blood, and there is more or less suppression. The temperature may rise gradually or suddenly and show marked daily remissions. Lumbar pain is uncommon, but abdominal pain and constipation are marked features of some attacks. The amount of dropsy present is very variable. Anæmia is of rapid onset and very pronounced. The pulse tension is raised and cardiac hypertrophy is soon established, sometimes dilatation ensues. In a favourable case some improvement occurs within a week, the secretion of urine increasing, but the hæmaturia and albuminuria take much longer to clear up. In some cases albuminuria persists and chronic interstitial nephritis may ensue. The duration of an average attack may be put at 7 weeks, but is subject to much variation. Broncho-pneumonia, pulmonary œdema, œdema of the glottis, and uræmic symptoms occur in severe cases. Convulsions may be recovered from, but coma is of bad augury. In some cases of scarlet fever œdema is said to occur without nephritis, or at all events without albuminuria.

Rheumatism.—This is a common complication, and usually makes its appearance towards the end of the first week. The arthritis is fleeting and mostly involves the hands and wrists, but pains in the shoulders and elbows are not infrequent. Joint effusions are not always present. The temperature

is somewhat raised. Sometimes the endocardium and pericardium are implicated, as in ordinary rheumatism, but the profuse sweats and creamy tongue are absent. Scarlatinal rheumatism is more common in adolescents and adults than in children. A mono-articular or multiple suppurative arthritis with, it may be, pyæmic manifestations is sometimes seen. It is believed to be streptococcal in origin. Sometimes the rheumatism is gonorrhœal.

Cardiac complications.—There are three groups: those due to toxæmia; those secondary to rheumatic or pyæmic complications; and those accompanying nephritis. The toxæmic effects are cardiac dilatation and acceleration of the pulse, which is so characteristic of this fever.

Scarlatinal rheumatism is occasionally the precursor of simple or more rarely of malignant endocarditis. An unfortunate feature is the tendency to pick out the aortic valves. The influence of nephritis in producing rapid cardiac hypertrophy or inducing dilatation has already been mentioned. Pericarditis may occur quite early in some cases of the septic type. The effusion is generally purulent.

Pulmonary complications.—Neither bronchitis nor broncho-pneumonia is common, but aspiration broncho-pneumonia may complicate septic cases. Edema of lungs may arise during the course of acute nephritis. Lateral sinus pyæmia may give rise to pyæmic infarction of the lungs, empyema and even pneumothorax. A primary empyema, often of insidious onset, occurs in some patients. Lobar pneumonia is a rare complication. Occurring early in the disease, it is streptococcal in nature and the prognosis is very grave.

Nervous complications.—If the delirium of onset, the nervous manifestations of uræmia and the cerebral complications of otitis be excluded, it may be said that nervous disturbance during the course of scarlet fever is rare. In those predisposed, epileptic fits may signalise the invasion. Hemiplegia with convulsive onset, incomplete paraplegia and peripheral neuritis have all been described. Chorea develops occasionally, usually in association with arthritis and endocarditis. Tetany sometimes occurs. Mental disturbance of a maniacal or melancholic type is an infrequent sequel, or may show itself during the acute stages.

On rare occasions gangrene of the extremities has been encountered. It is usually embolic in origin and leads to mummification, but gangrene of the legs has also been described as complicating scarlet fever in the subjects of congenital syphilis. Post-scarlatinal diphtheria was, in pre-antitoxin days, one of the gravest complications. Diphtheria may develop at the onset of the fever, but more often appears during early convalescence. It occurs more often in hospital-treated cases than in others. Every throat inflammation about the nature of which there is the slightest doubt should be subjected to bacteriological examination at once. This is a more rational procedure than the indiscriminate injection of all scarlatinal patients with diphtheria antitoxin.

Relapse.—A recurrence of the fever and rash before complete recovery from the initial attack occurs according to different authorities in from 0·5 to 7 per cent. of the cases. If the original attack were severe, the relapse is often mild, and vice versa. The sequels of a relapse are in nowise different from those of an ordinary attack.

Diagnosis.—Bacteriological identification of the *Streptococcus scarlatinae*.

is not sufficiently easy to afford much help in diagnosis. A positive Dick test before the third day of the attack is in favour of scarlet fever, since it indicates susceptibility, but a negative result does not exclude it. A positive Schultz-Charlton blanching test, made by the intradermic injection of 0.2 c.c. of a 1 in 10 dilution of immunised horse serum applied to the newly developed rash, is of more value. The reaction takes 8 hours to develop. The chief difficulty arises with mild attacks and with patients who come under observation after the initial stage. In the former the rash is evanescent, constitutional disturbance slight, and the tongue often atypical. A history of a previous attack is of great weight, but diagnosis can only be confirmed by the supervention of desquamation or of some characteristic complication. Sometimes the infection of a contact gives the clue. In days immediately following the rash significant signs are, slight staining of the trunk, faint striae in the flexures of the elbows, knees and groins, or a triangular patch of punctate erythema over Scarpa's triangle. The submandibular glands may be enlarged, and coarse papules resembling goose-skin present on the outer aspects of the arms and legs. The tongue has usually peeled by the fourth day and remains raw and papillated for about a week. Slight albuminuria, in the absence of diphtheria, is significant.

Desquamation of the typical pinhole type rarely occurs in other conditions than scarlet fever; the character of the accompanying symptoms and the time of appearance of the peeling must be taken into consideration.

Simple tonsillitis is distinguished by the absence of punctate rash, a tongue which remains heavily coated, and absence of desquamation. But an erythema may be present, with fleeting muscular pains and sometimes otitis, and even endocarditis or nephritis occur as complications.

Careful scrutiny of the body for a rash will usually prevent confusion with diphtheria. When faucial exudate is present in scarlet fever, it is usually softer and less coherent than in diphtheria, and any grey ulcerated areas are depressed below the general surface. In scarlet fever, too, the faucial pillars and soft palate may show the punctate rash, whilst pallor of the throat is more distinctive of diphtheria. In scarlet fever, febrile disturbance is more marked, initial vomiting is common, and delirium may occur. The fugitive erythema which sometimes appears on the chest in diphtheria is not punctate. Bacteriological examination is decisive, but the two diseases may coexist.

When influenza is rife, cases of scarlet fever are apt to be overlooked; but in influenza rashes are exceptional, and careful observation of the progress of the disease will soon lead to a correct diagnosis.

Lobar pneumonia may, in children especially, by its abrupt onset, high fever, vomiting and faucial inflammation, give rise to suspicion of scarlet fever, a suspicion favoured by the flushed face and circumoral pallor which may be present. But the throat affection is trivial, the respirations are rapid and accompanied by action of the *alae nasi*, and there is no punctate rash on the chest. Sooner or later consolidation of the lung may be detected, often in such obscure cases at the apex or high in the axilla.

Food, drug, serum and enema rashes often cause difficulty. Of drugs the most important rash-producers are copaiba and similar oleo-resins, quinine, antipyrine, the salicylates, aspirin and belladonna. Anomalous distribution or polymorphic character of the rash should at once arouse suspicion, especi-

ally so the discovery of urticarial wheals. The history and accompanying symptoms are of importance.

Erythema scarlatiniforme is characterised by a punctate eruption which is sometimes patchy and confined to the trunk. The rash is remarkably persistent, and desquamation may ensue whilst it is still in the florid stage. The peeling is profuse and the subjacent skin often erythematous. The characteristic sequelæ of scarlet fever are wanting. The disease is not known to be infectious and is very apt to recur, which gives a clue to its recognition. *Acute exfoliative dermatitis* is by some regarded as identical with it.

German measles in the scarlatiniform stage closely resembles scarlet fever. The diagnosis turns on the trivial character of the accompanying symptoms, which are chiefly catarrhal and the tender swelling of the mastoid and occipital glands. Even when the rash is scarlatiniform on the trunk, distinct morbilliform elements may often be recognised about the wrists and on the lower extremities, and this, with the history of an initial spotty rash on the face and around the mouth, is of great significance. The eyes are suffused and subsequent desquamation is insignificant. Sequelæ are practically unknown.

Measles is more easily distinguished. The rash is different and invades the face. Catarrhal symptoms are pronounced and Koplik's spots are present. Difficulty is only likely to arise in those cases of scarlet fever where a blotchy rash is present, or where the appearance of a septic rash may simulate intercurrent measles.

Prodromal rashes of a scarlatiniform type may appear in small-pox, chicken-pox and measles. In small-pox, the punctate rash is usually confined to the bathing-drawers area and to the axillæ. Sore throat is in favour of scarlet fever, whilst rigor and severe lumbar pain suggest small-pox. The eruption of the latter disease appears on the third day, and a doubtful case should always be isolated over that period. The initial rashes of small-pox are said to be absent in children under 10 years of age.

The eruption of chicken-pox may be preceded by a rash which is scarlatiniform, but it is more likely to be erythematous. The diagnosis turns on the condition of the fauces and tongue, the absence of the other signs of scarlet fever, and the speedy appearance of the characteristic vesicles.

As a prodromal rash in measles, a scarlatiniform eruption is decidedly rare. The marked catarrhal symptoms which accompany it will arouse suspicion, which is confirmed by the discovery of buccal inflammation and Koplik's spots.

Prognosis.—The mortality of scarlet fever varies with the type of the prevailing epidemic. Of late years, in Great Britain, a mortality of from 2 to 5 per cent. has been the rule. Of other factors, age is the most important, the mortality being greatest in infancy (21 per cent.), diminishing rapidly after the second year, and continuing to fall until puberty is reached, the least fatal period being from puberty to 36, after which age a slight rise occurs. The death-rate is slightly higher in males than in females. Tuberculous infections are likely to be lighted up by the infection, and puerperal patients run a grave risk of septicæmia. Chronic renal disease, if present, is likely to be adversely influenced.

Malignant attacks are very fatal, and the septic type of attack is also very serious, especially if broncho-pneumonia supervene. In adults, marked

sleeplessness and delirium are unfavourable signs, and in children, convulsions occurring after the initial stage. With regard to complications, nephritis in many instances clears up, especially if detected early and properly treated. Grave symptoms are uræmic convulsions, repeated vomiting and suppression of urine. Edema of lungs often precedes the fatal issue.

Of circulatory symptoms the occurrence of pericarditis is the worst. It is often purulent and may be associated with empyema. The danger of otitis media is remote rather than immediate in most cases.

Treatment.—*Prophylactic.*—Infectivity ceases mostly within a period of six weeks. Late desquamation of the hands and feet is not a source of infection, but discharges from the nose, throat or ear are dangerous. Convalescent carriers are responsible for something less than 3 per cent. of the cases treated in fever hospitals. The dangerous carrier is often characterised by unhealthy conditions of the nose, throat or ear, discharges from which may have re-appeared owing to the supervention of catarrh. Patients with persistent tonsillitis, rhinorrhœa or otitis should be isolated for at least 12 weeks from the commencement of the fever. The discharge of patients direct from wards containing others in the acute stage of the disease should be avoided; isolation for a day or two in a separate apartment is advisable. In cold weather the practice of bathing on the very day of discharge is not recommended, as a catarrh may be thus induced. Patients should not pass straight from isolation into the company of children and other susceptible persons.

Individuals in close contact with scarlet fever have at times been found to convey the infection, but a greater source of danger is the convalescent carrier, whose infectivity persists beyond the usually recognised period. The infectivity of such carriers has been known to last for weeks and even months; there is some evidence that it is intermittent.

The rules originally formulated by the Medical Officers of Schools may be taken as a safe guide in practice, i.e. isolation of the scarlet fever patient for not less than 6 weeks from the date of appearance of the rash, provided convalescence is complete and there is no evidence of inflamed throat or of discharge from the nose or ear, no suppurating or recently enlarged glands, and no eczematous patches about the nostrils, mouth or elsewhere. The quarantine period for contacts is 10 days, provided disinfection was efficiently carried out at the commencement of that period.

General.—Doubtful cases should be isolated until a definite diagnosis is made. Their premature transfer to a scarlet-fever ward is unjustifiable. Isolation of scarlet fever at home is most successful when a whole floor can be set apart for the patient and attendants, and there are no children of susceptible age in the house. The sick room should be large, light, freely ventilated and adequately warmed, the temperature being maintained at 55° F. to 60° F. according to the season.

The action of the skin is promoted by a daily wash and a tepid sponge every evening during the pyrexial stage. This may be replaced by a daily warm bath when defervescence is complete. The bed coverings should be adequate, but not too heavy. During convalescence, flannel or wool is the proper clothing; chill is by all means to be avoided. During the febrile stage the diet should consist of milk, barley water, or plain water and weak tea. When the temperature falls, beaten up eggs and farinaceous food may

be added and the diet gradually increased, nitrogenous food being allowed early in small amount. Most patients are fit for full diet within a week of the subsidence of the fever. Children, at all events, should be confined to bed for 3 weeks from the onset; by this means chills are avoided, the usual period of onset of nephritis passed, and the throat healed before the patient gets up. When the weather is warm, outdoor exercise may be allowed with advantage in the third or fourth week.

Special.—Attention should be paid to the mouth, teeth and gums, since oral sepsis is believed to bring its own train of local complications. The bowels should be regulated with mild aperients.

Concentrated anti-scarlatinal serum should be given early, in doses of 10 to 15 c.c., either subcutaneously or intravenously, according to the severity of the infection. To guard against anaphylaxis, a preliminary intravenous injection of $\frac{1}{10}$ c.c. in normal saline is advisable. In mild cases serum is unnecessary. The injection of 5 c.c. has been recommended for the purpose of producing a transient passive immunity in contacts.

Osman states that the incidence of nephritis is diminished if sufficient alkali is administered to keep the morning urine alkaline.

Pyrexia, with its accompanying restlessness, insomnia and delirium, may be controlled by tepid sponging and the use of acetyl-salicylic acid, chloral-amide or paraldehyde. A cold pack at 60° or 70° F. for 15 or 20 minutes is very beneficial when nervous symptoms are pronounced. After the middle of the second week, if albuminuria be present, cold sponging and cold packing should be avoided.

Persistent vomiting may be controlled by the use of diluted or citrated milk or temporary substitution of albumin water. Tincture of iodine in doses of 3 or 5 minims is often efficacious. When swallowing is painful the feeds should be small and often repeated. For the local treatment of the throat and nose, gargles are quite ineffective, and sprays have but little cleansing influence. Alkaline carbolic, permanganate or boric lotions should be applied by gentle syringing or through a douche-can under low pressure. The syringe nozzle, which should be short, is passed into the mouth behind the back teeth, the patient lying on the side with the head low. It may be necessary to envelop children in a large towel which secures the arms. For very septic and offensive throats a free chlorine lotion should be used every 2 or 3 hours. It is made by putting 200 grains of potassium chlorate in a large dry bottle, pouring on it 40 minims of strong hydrochloric acid, and setting aside, loosely corked, for 10 minutes; a pint of water is then added in 4 or 5 successive portions, shaking well. An equal quantity of water should be added to this solution before use. Great gentleness should be exercised if the nose be syringed; it is generally unnecessary. Ointment should be applied to the nares and upper lip to prevent excoriations.

Secondary tonsillitis is treated on ordinary lines, but care must be taken not to overlook secondary diphtheria. If adenoids and enlarged tonsils delay convalescence, their removal gives good results. Cervical adenitis is best treated by smearing glycerine on the neck and applying cotton wool. Poulting is rarely called for; it appears to precipitate suppuration. Inflamed glands should only be incised when the presence of pus is assured; premature incision is to be avoided. In every case of scarlet fever care should be taken that the ears are clean. The pain of otitis may be mitigated by

syringing with water as hot as can be borne and the application of hot, dry cotton wool, or a rubber hot-water bottle, to the side of the head. By some the instillation of a few drops of glycerine or carbolic acid and the use of fomentations are recommended. Incision of the tympanic membrane is the most efficient method. Discharging ears should be cleansed frequently with hydrogen peroxide and never tightly plugged. After the fourth week of the fever, removal of adenoids and infected tonsils shortens the duration of discharge. Watch must be kept for mastoid tenderness and cedema.

Scarlatinal rheumatism is usually mild and transitory; salicylates or acetyl-salicylic acid give relief. When joint swellings persist, a mild pyæmic condition is often present or an unsuspected gonorrhœa. When the presence of pyæmic arthritis is suspected an exploratory aspiration under strict asepsis may be advisable.

Scarlatinal nephritis.—The importance of daily examination of the urine and avoidance of chill must be emphasised. No patient with albuminuria should be allowed up. During the acute stage of nephritis the diet should be limited to milk and barley water. In very acute cases, water only may be given for 24 hours or even longer. The patient should be clothed in flannel and lie in blankets. The bowels should be regulated with salines or compound jalap powder; constipation is often troublesome. Action of the skin should be encouraged by simple diaphoretics and the use of an incandescent electric bath, if available. Acetyl-salicylic acid is useful in promoting sweating. For uræmia, free purgation and sweating should be induced; venesection is useful in older patients, coupled with saline infusion. Repeated uræmic convulsions call, in addition, for chloral or chloroform. Lumbar puncture may have a good effect. Morphine if used must be given with caution.

Grave heart failure is encountered in malignant scarlet fever and during the course of septic or toxic attacks. Strict recumbency is essential. Strychnine in doses of gr. $\frac{1}{60}$ every 2 or 3 hours is often used, but even more effectual are injections of adrenalin or pituitrin. Diffusible stimulants such as ammonia and ether mixture, and brandy or champagne, are of value. Oxygen inhalation, hot saline by the bowel, or glucose enemata (5 per cent.) are useful accessories.

FOURTH DISEASE

Clement Dukes described an infectious disease which he considered distinct from scarlet fever and rubella. Its characteristics are the following:

It is most prevalent in spring and summer. Previous attacks of scarlet fever and of rubella afford no protection from it. Premonitory symptoms are generally absent or trivial, the first sign usually being a rosy red rash, slightly raised, which covers the whole body in a few hours. The temperature may range from normal to 103° or even 104° F. The fauces are red and velvety, the tongue clean or slightly furred, and the pulse only accelerated in proportion to the temperature. The posterior cervical, axillary and inguinal lymph glands are enlarged to the size of peas, hard and somewhat tender. The conjunctivæ are pink. Desquamation may ensue and is sometimes free.

The incubation period is between 9 and 21 days, and infectivity lasts for 2 or 3 weeks.

Most authorities either reserve judgment or refuse to recognise such a disease, alleging that some of the cases are rubella with scarlatiniform rash and some mild scarlet fever.

INFECTIOUS ERYTHEMA

This is a feebly infectious disease characterised by an erythematous rash which usually starts on the face, avoiding the circumoral region and then spreads to the limbs, where it assumes the form of large, rounded, slightly raised patches which spread at the periphery and fade at the centre (erythema marginatum). It has a predilection for the extensor surfaces and extends downwards. The trunk is seldom invaded.

The incubation period is 6 to 14 days, and the rash persists for a week or more. Constitutional symptoms are absent.

SMALL-POX

Synonym.—Variola.

Definition.—An acute, specific, highly infectious fever, characterised by a definite incubation period and a distinctively distributed, deep-seated eruption which passes through the stages of papule, vesicle, pustule and crust. The fever shows two phases—a remission being followed by a re-accession on the onset of the pustular stage.

Ætiology.—All races, both sexes, and persons of every age are susceptible if unprotected by a previous attack, or by efficient vaccination. This general liability is most evident when the disease is for the first time introduced into a new community; under such conditions it may decimate the population. Its present-day incidence on adults is accounted for by vaccination in infancy; in endemic centres it was, prior to the introduction of vaccination, a disease of early childhood. Small-pox has at times been epidemic in every civilised country, following trade routes and the channels of communication. It is more severe in hot climates. Coloured races are said to take it badly. Unlike scarlet fever and measles, it frequently attacks infants at the breast. When the disease occurs in severe form during pregnancy, abortion or premature delivery is inevitable, and in less severe attacks the same accident is likely. Few of the children born in these circumstances survive, sometimes they actually show the rash or its scars at birth.

In England and temperate climes most outbreaks occur during the winter and spring, and tend to die out with the commencement of summer. Small-pox protects against itself, and second attacks are rare. Vaccination gives complete immunity for some years and partial immunity usually persists afterwards. Complete natural immunity is very rare, but is reported. Inoculated small-pox affords more complete immunity than vaccination.

Infection with small-pox is, almost certainly, through the respiratory tract, and may be direct or indirect, i.e. by contact, which need not be very close, with a patient suffering from the disease or through the medium of objects infected by the sick person. Intermediaries may carry the contagion in their clothing or in their hair. The greater incidence in the neighbourhood of small-pox hospitals suggests the possibility of aerial convection of

the virus for considerable distances, perhaps exceeding a mile, but the influence of human carriers in these cases is hard to eliminate. Bedding, clothing and rags may retain their infectivity for considerable periods of time, especially when stored. Transmission by flies and domestic animals is regarded as a possibility. The infectivity of small-pox is slight at the time of the symptoms of onset, and is much greater when the eruption appears. It continues until all the scabs have separated. The virus is very resistant and long persists in the dry scales and crusts shed from the body. Corpses of those recently dead from small-pox can transmit the disease. Tramps are often responsible for the conveyance of infection from one locality to another.

There can be no doubt that small-pox is due to a living organism, but whether this is bacterial or protozoal cannot, with present knowledge, be decided. Minute, but characteristic, intracellular bodies are found in the epithelial cells of the pocks of small-pox and vaccinia, and also in the cornea of the rabbit, after scarification with the virus of these diseases. They are known as *Guarnieri bodies* and, although at one time thought to be protozoal (*Cytoryctes variolæ*), the trend of modern opinion is to regard them as a special degenerative reaction of the epithelial cells in the presence of the virus of small-pox or vaccinia.

Pathology.—The cutaneous lesion of small-pox lies in the deeper layers of the epidermis. Vesiculation is due to serous exudation between the cells. Loculation is caused by vertical strands of degenerated epithelial cells which radiate from the base of the pock. The tenseness of the vesicle and tethering of the covering by this reticulum cause the pock to be umbilicated. In malignant attacks, where the pocks are flaccid, and in the old and debilitated where a similar condition may obtain, umbilication is often absent. With pustulation the fibres of the reticulum are ruptured and the pock becomes dome-shaped. The suppuration is attributed to secondary infection with extraneous organisms, particularly with streptococci. On mucous membranes, owing to the absence of a resistant horny layer and maceration by the secretions, the vesicles rupture almost as soon as formed and are rapidly converted into shallow ulcers. The chief change in the blood is an increase in the mononuclear elements, which is coupled with great activity of the lymphocyte-producing tissues throughout the body. There is a great paucity of polynuclear cells. The post-mortem appearances are those usually found in acute infective processes. The rash persists, the liver is often much enlarged, and the spleen swollen. Particular attention has been drawn to the presence of local necroses in the liver, testicles and bone marrow. These are often infiltrated with mononuclear basophil cells. In hæmorrhagic small-pox, petechial and purpuric hæmorrhages are found in the skin, mucous membranes, lungs and other viscera, sometimes also in the retro-peritoneal tissues and the roots of the mesenteries.

Symptoms.—*Unmodified small-pox.*

Period of incubation.—Taking the first symptoms of invasion, this is from 10 to 14 days. The average period is 12, or counting to the appearance of the rash, 14 days. Extremes of 5 to 23 days are mentioned but are rare. In inoculated small-pox the generalised eruption appears on the eighth to the eleventh day.

Period of invasion.—In a typical attack the invasive symptoms are sudden

and of great intensity. The most prominent are severe chills or rigors, marked pyrexia, severe frontal headache and intense pain across the loins. The temperature quickly reaches a maximum of 103° to 104° F., and is accompanied by severe prostration. Giddiness and nausea are present and vomiting may occur, particularly in children. Delirium, mental symptoms and even suicidal tendencies may accompany the invasive stage. With these severe symptoms are coupled more ordinary febrile manifestations, such as anorexia, thirst, coated tongue and disturbed sleep. The breath is offensive, the skin usually hot and dry but sometimes perspiring, and the bowels constipated. There are, however, mild attacks in which the symptoms of invasion are much less severe, and even in more severe attacks pain across the loins is not always present. Mild invasive symptoms usually presage a mild eruption; with a severe invasion the attack is generally, although not invariably, grave.

Prodromal rashes.—These may precede the proper eruption for 1 or 2 days. They are not always present. There are two types, one purely erythematous, the other petechial or hæmorrhagic with or without accompanying erythema. The pure erythemas are of a bright red or dusky purplish colour and may appear on the trunk, where they are often patchy, or be limited to the bony prominences and extensor surfaces of the limbs. They may suggest the rash of scarlet fever or bear a superficial resemblance to that of measles. The hæmorrhagic or petechial rash, which often has at first a dusky erythematous background, is more characteristic. It appears in the flexures of the groins which are stippled with small petechiæ; it invades the thigh for an inch or two and extends in an ill-defined manner on to the abdomen. Sometimes it extends towards the axilla and may be found on the back of the neck and flexures of the knees. The petechial rashes are persistent and indicate a severe attack. The erythemas are fugitive and of good prognostic import; the only exception is a very brilliant universal erythema of face, trunk and limbs which sometimes ushers in hæmorrhagic small-pox.

The eruption.—On the third day the symptoms of invasion are at their maximum and the eruption appears, showing first on the forehead and temples near the edge of the hairy scalp and also on the wrists. It extends rapidly over the body but always affects most the parts usually uncovered and those most exposed to pressure, friction or other irritation. It is least profuse on the abdomen and in the groins, somewhat more marked on the chest, still more marked on the back, especially across the shoulders, thicker still on the arms, choosing their distal portions, and most profuse of all on the face, especially its upper part. It reaches the lower extremities within 24 hours of its first appearance. Meantime the lesions multiply on the parts already affected, the eruption becoming thick on the face, and perhaps in the scalp, whilst still scanty on the parts invaded later. By the third day it will have attained its full density, but the earlier lesions will be in a slightly more advanced stage of development than those which appeared later.

It conspicuously avoids depressions, flexures and protected flexor surfaces, such as the armpits, flanks, groins, orbital hollows and supra-clavicular depressions. The escape of the axillæ and scantiness of rash on the flanks is marked. Abnormal irritation by clothing, irritants or scratching may determine increased local density of the eruption. The pocks are aggregated over prominent bones and outstanding tendons, but the clavicles and

malleoli are exceptions to this rule. The rash is more or less symmetrical; one arm will not escape when the other is involved.

On the first day of efflorescence the rash consists of small dull-red macules. Within 24 hours these are becoming obvious papules which feel shotty when pinched up between the finger and thumb, the hardness being best marked on the face, hands and forearms. On the third day of eruption many of the papules have become converted into vesicles, but the commencement of vesiculation may be recognised on the summits of the papules at an even earlier stage. By the fourth or fifth day the eruption is completely vesicular and the early toxic symptoms and fever may have entirely subsided. The vesicles, which are circular in outline, slowly increase in size and become surrounded by an inflammatory areola. They are now about the size of split peas, greyish in colour, and set in the skin rather than on its surface. Umbilication is evident and loculation is proved by their failure to collapse when transfixes by a sterile needle. The contents of the vesicles remain clear for 24 hours only; they then gradually become purulent, so that by the fifth day pustules are in evidence on the face and by the eighth day are universal. With pustulation, the pocks soften, become flat-topped and lose their areolæ. Reaccession of fever with constitutional symptoms and often delirium, the secondary suppurative fever, accompanies the process of suppuration or maturation. Where the pustules are plentiful a marked inflammatory œdema of the skin may now appear, causing the features to become much swollen and impeding the movements of the hands and fingers. Much tenderness accompanies this œdema, and the patient may also be tormented by itching. Suppuration destroys the loculation of the vesicles and also obliterates umbilication. Adjacent lesions, particularly on the face and hands, may run together in the vesicular and pustular stage—a process which produces the confluent rash, and is a sign of severe infection. On the ninth and tenth day of eruption the pustules begin to desiccate and scab, some first rupture or are torn by scratching, and collapse. Brown or black crusts result which separate by the end of the thirteenth or fourteenth day, but where the skin is very thick, as on the palms and soles, the dried-up unruptured pustules may form deep-seated “seeds” which may take weeks to work their way to the surface.

To summarise: the rash is papular on the first to the third day; vesicular from the third to the fifth; pustular from the fifth to the ninth, and desicating from the ninth to the seventeenth.

The cutaneous eruption is accompanied by an outcrop on the mucous membranes of the mouth, nose and pharynx. In severe cases the larynx, bronchi, gullet and even the stomach may also be affected. On the mucous membranes vesicles are soon transformed into shallow grey ulcers. Vesiculation may be observed on the palate, whilst the lesions are still indeterminate on the skin. In consequence of the eruption the fauces and tongue become sore, the nose is obstructed and deglutition is painful. Implication of the larynx will cause hoarseness or aphonia and even dangerous œdema. The mucous membranes of the vulva, vagina and rectum may also be involved.

The fever (Fig. 4) of invasion reaches its acme with the appearance of the rash, then it falls, but not immediately. It is generally normal by the fifth day of the eruption, often before this. It is at this stage, in the milder attacks with

scanty rash, the patient may attempt to resume his ordinary occupation, and, in modified cases, very little further febrile disturbance may ensue. Ordinarily, however, the secondary suppurative fever now sets in and reaches its acme about the ninth or tenth day of the eruption. Its duration in the more severe cases is from 10 days to a fortnight. In severe and confluent cases, the remission of temperature in the vesicular stage may be ill-marked or absent. The pulse and respirations are quickened proportionally to the degree of fever present, but in grave cases the respirations become shallow and irregular, and the pulse accelerated and feeble.

The urine is febrile in character. Some albumin may be present, and a diazo-reaction may be obtained. A foul odour may emanate from the skin in suppurative confluent cases.

Owing to the deep-seated position of the lesions in the skin, depressed scars are left, the amount of pitting depending on the degree of suppuration.

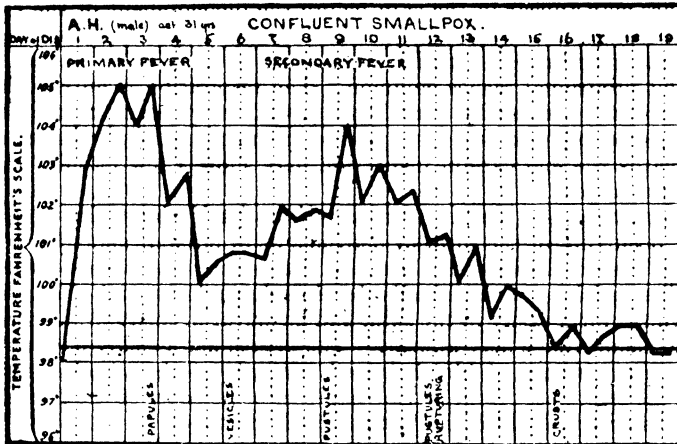

FIG. 4.—Confluent small-pox in an unvaccinated adult.

The pits show a reddish staining which may persist for months. Some desquamation may accompany the separation of the crusts, particularly on the feet and hands. The hair often falls out freely. Convalescence is, in favourable cases, rapid and complete.

Modified small-pox or varioloid.—Small-pox of a very mild type may occur both in the vaccinated and the unvaccinated. In such cases initial symptoms may be slight, and the eruption, although typical, is scanty; sometimes it altogether fails to appear. More commonly, especially in vaccinated subjects who retain but partial protection, the initial symptoms are severe, and the rash appears early, but it is generally sparse and discrete, tends to evolve quickly, and many of its elements fail to progress beyond the papular or vesicular stage, the suppurative fever being slight or absent. The lesions, which are often small, are superficial and may be unilocular, sometimes they appear fleshy and wart-like. The modification is most evident on the face. In such cases the arrest of development leading to the juxtaposition of papules,

vesicles and small pustules may cause a resemblance to chicken-pox, but the distribution remains characteristic.

Severe types of small-pox.—These comprise the confluent and hæmorrhagic varieties. *Confluent small-pox* is characterised by fusion of the lesions, particularly on the face and hands. The rash may fuse whilst still papular, but more commonly does so in the vesicular and pustular stages. In such cases the toxæmia is severe and the remission of symptoms before the stage of pustulation may be absent or ill-marked. Delirium is common, and the secondary fever high. Inflammatory œdema is very marked, the features may become quite unrecognisable and the confluent pocks may form a continuous sheet of pus. Severe conjunctivitis, salivation, cough, aphonia and diarrhœa are common. Some patients pass into a typhoid condition. An offensive odour emanates from the skin, circulatory failure is progressive, and death may occur towards the end of the second week.

Hæmorrhagic small-pox.—In the most malignant variety, purpuric flecks and patches may appear in the skin before the development of the eruption and are accompanied by subconjunctival hæmorrhages and bleeding from the mucous membranes. Initial symptoms, in particular backache, are severe, and prodromal rashes common. The respiration is hurried, but the temperature not necessarily very high. Death may occur before the outbreak of the proper eruption gives a clue to the nature of the infection, but often towards the end careful inspection may show a few papular elements struggling to appear.

In other cases the bleeding first manifests itself about the time of the eruption, occurring in the form of petechiæ or of circular spots between the lesions and also infiltrating the bases of the vesicles and staining their contents. The vesicles are often badly developed, confluent and of a violaceous hue. Bruises form easily in the skin, and hæmaturia, epistaxis, hæmatemesia or uterine hæmorrhage may appear. The breath has a sickly odour.

The mere presence of blood-stained contents in the vesicles, especially those on the legs, apart from hæmorrhages into the bases of the pocks, in the skin and elsewhere, is not of bad prognostic importance.

Anomalous types of small-pox.—There have occurred, especially in Brazil and the West Indies, but also in Africa, Australia and parts of Europe, outbreaks of an infectious disease bearing a resemblance both to small-pox and chicken-pox. This is variously known as alastrim, amaas, and varioloid varicella. The names para-variola and variola minor have also been suggested. It is now looked upon as a variety of small-pox, from the ordinary form of which it differs in its mild course and low mortality, and the fact that it attacks adults rather than children. The lesions are superficial, their appearance may be delayed and their evolution is more rapid than in small-pox, but their distribution is similar. The vesicles have a chalky appearance, are often unilocular and not umbilicated. The resulting crusts are amber-coloured. Although the invasive symptoms may be rather sharp and accompanied by vomiting, there is no secondary fever, and the protective power of vaccination is not so definite as in ordinary small-pox—indeed, it is possible to vaccinate successfully some of the victims during convalescence.

Complications.—During the later stages and in convalescence, boils and superficial abscesses often cause trouble. Septic rashes, erysipelatous or impetiginous infections may spread from the pocks. The cervical and

axillary glands may become enlarged or even suppurate. In the more severe cases, bed-sores may rapidly form over pressure points. Rarely death is due to septicæmia arising from these cutaneous affections.

Ocular complications are important. Conjunctivitis is common. Pustules may form on the palpebral or ocular conjunctiva. The eyelids often become inflamed and oedematous. A rapidly spreading keratitis may lead to sloughing of the cornea, but corneal ulcers are more common and sometimes lead to perforation and panophthalmitis. Iritis is rare. Retinal hæmorrhages sometimes cause blindness. The scars of the corneal ulcers may much impair the sight. Otitis media is comparatively common.

Laryngeal inflammation may be so severe as to necessitate tracheotomy, and may lead to perichondritis and necrosis. Bronchitis and bronchopneumonia are frequent and often accelerate death. Lobar pneumonia and purulent pleurisy are rare. Endocarditis and pericarditis are exceptional, but degenerative changes in the myocardium are not infrequent. Occasionally a destructive arthritis supervenes; it is said to be more common in childhood. Although albuminuria is often found, a true nephritis is rare.

Parotitis is looked upon as a secondary duct infection from the mouth. Orchitis sometimes occurs during the acute stage.

In rare cases paralysis of the extremities and of the bladder has been noted. Ataxy and articular defect may supervene, and sometimes hemiplegia occurs. The underlying lesions may be peripheral neuritis, patchy myelitis or encephalitis.

Disfigurement of the face, permanent blindness, deafness and sometimes alopecia may be the legacies of a severe attack.

Diagnosis.—The whole body should be stripped and examined in a good light. In some cases a preliminary bath is needful. Attention should first be focused on the distribution rather than on the characters of the rash. Too much reliance should not be placed on shottiness or umbilication. The condition as to vaccination should be ascertained and the nature of any prevailing epidemic borne in mind.

The initial fever may itself lead to difficulty in diagnosis; the symptoms of onset are somewhat similar to those met with in other acute diseases, particularly influenza, pneumonia and cerebro-spinal fever. Severe prostration and backache, when present, are suggestive. Often the diagnosis is not certain until the true eruption appears, but the appearance of a petechial prodromal rash in the groins may enable earlier recognition. As regards influenza, it is more common for small-pox to be at first mistaken for this disease than for the converse to occur. Lumbar puncture is available in cerebro-spinal fever. In pneumonia sooner or later lung signs appear. Precipitate certification of a supposed case of small-pox, even in a contact is unwise; it is better to await the appearance of the rash, remembering this should appear first on the forehead, near the roots of the hair, the cheek bones, sides of the nose, wrists, hands and forearms. The interior of the mouth should also be inspected and any parts of the skin which have been subjected to special irritation.

The prodromal rashes, if purpuric, may be confused with different varieties of purpura, if erythematous, with scarlet fever, measles, rubella, urticaria or other forms of erythema.

The characteristic groin incidence of the purpuric rash of small-pox should

be remembered, and is of great assistance in diagnosis. More widespread purpuric rashes, however, are at times misdiagnosed as febrile purpura until the occurrence of small-pox in contacts reveals their true nature. Conversely, febrile purpura and purpuric rashes occurring in ulcerative endocarditis, cerebro-spinal fever and other conditions may be mistakenly thought to indicate small-pox. The distribution of the rash and the character of accompanying symptoms should be noted. Physical examination of the organs may reveal signs which help to clear up the diagnosis, which may be very difficult.

A scarlatiniform prodromal rash is distinguished from scarlet fever by the absence of tonsillitis and of punctate redness of the soft palate. The rash on the skin is not definitely punctate and the area of circumoral pallor wanting. The tongue is not typical nor are the tonsillar lymph glands enlarged.

Morbilliform prodromal rashes bear only a very superficial resemblance to measles. The diagnosis is discussed later. Nor should rubella be confused if its characters be borne in mind. The initial erythema may resemble those induced by antitoxic serum, by soap enemas and by drugs. The characters of these rashes are given in the article on scarlet fever.

The true eruption of small-pox may be confused with measles, chicken-pox, perhaps typhoid or typhus, also with various forms of papular erythema, urticaria, acne, papular and pustular syphilides, and glanders. Sometimes drug rashes, particularly those due to iodides, lead to mistakes. Measles on the face may bear a close resemblance to the papular eruption of small-pox. It is distinguished by the catarrhal symptoms, Koplik's spots, the distribution of the rash on the body, and the fact the temperature tends to rise as the eruption increases instead of falling as it does in small-pox.

The differentiation of some cases of chicken-pox is a great source of difficulty. For although chicken-pox is a disease of childhood whilst small-pox now chiefly affects adults, yet cases of chicken-pox in the adult are not infrequent, and in them the prodromal symptoms may be sharp and the rash not appear until the second or third day. Chicken-pox presents the following distinctive characters:

1. The rash of chicken-pox appears first on the trunk, and is thickest on the trunk, face, upper arms and thighs. It avoids the extremities of the limbs. It does not especially select irritated areas, nor does it avoid the axilla and groin. The presence of many lesions on the palms and soles is greatly against chicken-pox.

2. The eruption comes out in distinct crops over 3 to 5 days or more.

3. The vesicles develop much more rapidly and are mature in 24 hours.

4. The lesions are superficial and unilocular, rarely umbilicated. Their bases are not indurated. Near flexures they may assume an oval outline, sometimes they are irregular or crenated.

5. Pocks of all stages of development may be present at the same time on a given area of skin.

6. The lesions are smaller. Pustules and scabs half an inch across are almost certainly due to small-pox.

7. Successful vaccination within 5 years or revaccination within 10 years is evidence against the disease being small-pox. Chicken-pox does not protect against successful vaccination in an unprotected individual. If the

disease be small-pox, vaccination will prove unsuccessful. This rule, however, is not absolute. Vaccination may prove successful in anomalous forms of small-pox, and has been alleged to take in ordinary small-pox on rare occasions.

Confusion with typhoid and typhus is uncommon, and should be eliminated by taking into consideration the distribution of the rash and character of the other symptoms. In distinguishing other skin eruptions it should be remembered erythemas are often polymorphic. They may show occasional vesiculation which is quite superficial and are sometimes febrile. Acne affects the face, shoulders, back and chest; it is chronic, afebrile, and often associated with comedones and scars. The lesions may be pustular but are never vesicular. The lesions are not found on the forearms or hands.

If syphilis be borne in mind its eruptions are not likely to be mistaken. Reliance must be placed upon their distribution, polymorphic character, other signs of syphilis, the history and the Wassermann reaction. A patient with syphilis may also have small-pox. Glanders is rare, but when the nodules on the face suppurate and are accompanied by fever, small-pox may be suggested. There is usually a nasal discharge and a history of association with horses. Bacteriological examination will show the *Bacillus mallei*.

Certain laboratory tests have been elaborated for the detection of small-pox. Of these, Paul's test is of value. It is carried out as follows. A rabbit's eyes are cocainised. One is scarified with the contents of a suspected pock, the other is simply scarified as a control. At the end of 48 hours the rabbit is killed and the eyes are examined in a sublimate bath. In the case of small-pox or vaccinia, but not of chicken-pox or other vesicular eruption, the inoculated cornea shows opaque white elevations on a milky background. The other cornea is evenly opaque without epithelial plaques. Guarnieri bodies are present in the plaques. A more certain test and one more easy to apply and appraise is intradermal inoculation of the rabbit with material from a small-pox vesicle. After a short incubation period a characteristic inflammatory reaction ensues. This reaction remains in abeyance when serum from a rabbit hyperimmunised with vaccinia virus is mixed with the small-pox material before injection into the dermis (Ledingham, Defries and McKinnon). Other tests depend on the production of allergic reactions, as, e.g., when small-pox material is inoculated intradermally into a rabbit which has been hyperimmunised with vaccinia virus.

Prognosis.—Natural small-pox has a mortality which varies from 25 to even 40 per cent. The prognosis may be considered under the following heads: (1) The vaccinal condition of the patient; (2) the age; (3) the nature of the attack; and (4) the character of the prevailing epidemic.

1. When a vaccinated person takes small-pox the nature of the attack usually indicates some residual immunity, the severity of the disease being less and the mortality much lower than in the unvaccinated. The presence of large, well-foveated vaccination scars renders the prognosis very favourable. After the age of 15 the protective influence of infantile vaccination will to a large extent have disappeared, but revaccination at puberty, properly performed, confers a high degree of immunity for the rest of life.

2. The death-rate in the first 5 years of life is very high and may exceed 40 per cent. After that there is a fall, at first gradual, then considerable, up to the age of 15 or 20, which is the most favourable period. Subsequently

the mortality rises steadily and may even exceed the figures given for the first quinquennium. In the vaccinated, however, the younger the patient the more certain is recovery. If revaccination has not been performed, as age increases the mortality does so also, and may reach 15 per cent. in persons over 30 years of age.

3. The nature of the symptoms is important. Mild invasion presages a mild attack. Severe invasive symptoms usually, but not invariably, mean a severe infection, but they may precede mild attacks in the vaccinated and sometimes in others. Prodromal rashes of a vivid lobster hue, especially if petechiæ be present, are the heralds of grave, often hæmorrhagic infections. Very intense backache is also an ominous invasive symptom. The more profuse the pustular rash the worse the prognosis, but the intensity of the suppurative stage is much modified by previous vaccination. Confluent eruptions mean a bad outlook, whilst patients in whom the rash remains discrete usually recover. Hæmorrhagic small-pox is always fatal.

Other unfavourable symptoms are incomplete remission between the primary and secondary fever, sleeplessness, active delirium, especially in drinkers, considerable implication of the larynx and broncho-pneumonia. The influence of pregnancy in inducing abortion and miscarriage has already been mentioned.

4. Epidemics vary much in their severity and mortality. In some the disease is so slight and the mortality so low, that doubts arise whether the epidemic is really small-pox.

Treatment.—*Prophylactic.*—Efficient vaccination and revaccination are the most powerful safeguards. The chief measures to be taken when the disease is recognised are the following: (1) Prompt removal of the patient to an isolation hospital. (2) Thorough disinfection of infected rooms and clothing. (3) Immediate vaccination or revaccination of all other members of the household and of contacts. Four or even more days after exposure vaccination may prove effectual in preventing the disease, at all events will modify it. (4) Quarantining of contacts for 16 days, or a daily inspection so that initial symptoms may be detected at once. (5) Notification of schools or institutions attended by inmates of the same house.

Inoculation with small-pox, which prior to vaccination was a method of prophylaxis, is said in some instances to have had a mortality of 2 or 3 per cent.; but even this compares favourably with a mortality of 50 per cent. as seen in some epidemics of ordinary small-pox. Inoculation, however, was found to spread the disease, and so has, in England, been made a penal offence.

General.—This is purely symptomatic. Abundance of fresh air, cool surroundings, and not too great a weight of bedclothes, fluid diet, regulation of the bowels, and tepid sponging night and morning form the regular routine. The mouth should be cleansed regularly with peroxide of hydrogen, alkaline carbolic lotion, or some other mild antiseptic, and the nose gently douched or liquid paraffin instilled. A water pillow may be necessary in some cases. Severe pain in the head and back during the invasive stage may be mitigated by the application of an ice-bag to the scalp and use of fomentations to the back; at the same time aspirin, phenacetin, or chloral and bromide may give relief; but the drug most generally useful, both in this stage and in the sleeplessness, delirium and discomfort of the secondary fever, is opium in the

form of 10 grains of Dover's powder. Sometimes paraldehyde is effectual. Delirious patients should never be left alone. The intractable vomiting of the early stage is allayed by citrating or peptonising the milk or substituting ice and champagne. Tincture of iodine in 5-minim doses is also useful. When fever continues high and is accompanied by toxæmia and delirium, tepid sponging may be replaced by hot or cold packs with advantage. Many methods have been tried of aborting the eruption and preventing the subsequent pitting. None are effectual. Evacuation of the contents of the pocks as soon as fluid appeared in them used to be recommended. Some advocate painting the face with tincture of iodine, diluted if painful, twice a day for the first 8 or 10 days, and then applying vaseline; or, better, a saturated (5 per cent.) solution of potassium permanganate may be painted over the whole body three times a day until scabbing begins, and afterwards less frequently. The application of a lint mask soaked in glycerine is useful, and glycerine may also be applied to the hands, or a dilute carbolic compress substituted. When the eruption is thick in the scalp it may be necessary to cut the hair short. The administration of salol in 10-grain doses every 4 hours is believed to modify the pustular stage. An attempt to combat the amount of suppuration by exposing the patient to red light, whereby actinic rays are cut off, is recommended by Finsen, but is said to prove too depressing. To mitigate the offensive odour which emanates from the skin, dilute carbolic lotions may be used (they also relieve the itching), or creosote may be vapourised in the sick-room. Starch poultices and alkaline washes are used for the removal of refractory crusts and zinc ointment applied. The eyes require special attention; they should be bathed with boracic lotion at frequent intervals, and dilute nitrate of mercury ointment smeared on the edges of the lids. Should keratitis threaten, an ointment of atropine with yellow oxide of mercury should be applied.

Laryngitis calls for a steam tent and inhalations of benzoin or lysol. Heart failure is combated by the usual methods, and strychnine is useful as a nervous and respiratory stimulant. During decrusting and convalescence frequent warm baths are grateful, and quinine is a useful tonic.

Patients are to be regarded as infectious until the scabs are all separated and the skin quite healed.

VACCINIA

Vaccinia or cow-pox, a disease which at one time was very prevalent among cows, but is now rare, is characterised by a vesicular eruption on the udders and teats. The vesicles, which are surrounded by an inflammatory areola, may by rupture form extensive irregular ulcers. Abrasions on the hands of milkers may be accidentally inoculated from these lesions and they, in turn, may inoculate other cows in the herd. The hands of the infected milker show vesicles with surrounding induration, the axillary glands become swollen and there is some fever. Individuals thus inoculated are protected from small-pox, and Edward Jenner made practical use of this fact by inculcating the practice of deliberate vaccination and transference of the virus from arm to arm. In addition he demonstrated that those thus inoculated were refractory to subsequent deliberate inoculation with the virus from small-pox lesions.

After long dispute, the question of the actual identity of cow-pox and small-pox has practically been settled by animal experiment in favour of Jenner's view that the two diseases are one and the same, small-pox virus being so attenuated and modified by its transmission through the cow that its inoculation results only in a local lesion, a lesion which, however, affords a high degree of protection against subsequent attacks of small-pox. *Vaccinia* also differs from small-pox, whether the latter be natural or deliberately inoculated, in that it has lost its infective character, and so can be used for purposes of vaccination without risk of propagating small-pox in the community. We may define *vaccinia* as *variola* which has been modified by transmission through cows or calves.

The histology of the vaccine vesicle is in every respect comparable to that of the lesion of small-pox. It goes through the stages of papule, vesicle and pustule; and loculation is produced owing to the persistence of the remnants of vacuolated epithelial cells in the form of septa.

For the purpose of vaccination vaccine lymph is prepared by the inoculation of healthy calves, the contents of the vesicles being collected and freed from pyogenic and other extraneous organisms by admixture with glycerine. This process of glycerinisation kills most of the adventitious germs, but leaves the virus of *vaccinia* uninjured. The lymph thus prepared is stored in capillary tubes and will remain efficacious for at least 8 months. Its use is preferable to the direct inoculation from human vaccine vesicles.

The operation of vaccination is carried out as follows: An area of skin over the insertion of the left deltoid muscle or on the outer side of the thigh is carefully cleaned with soap and water, and afterwards with ether. The contents of a tube of lymph are then ejected on to the cleansed area in 2, 3 or 4 separate portions, according to the number of insertions proposed. Scratches are made through the drops of lymph with a sterile lancet or sterile needle, care being taken to avoid drawing blood, and the lymph gently rubbed over the scratches with the instrument used. The scarified spots should be at least an inch distant from each other to avoid confluence. The lymph is given a few minutes for absorption, and any excess is removed with sterile wool. The scarified area is covered with sterile gauze. The whole procedure must be carried out with strict regard to asepsis.

If the operation be successful, inflamed areas appear at the sites of inoculation, and by the third day become distinctly papular. By the fifth day, small clear vesicles have formed which slowly increase in size and become depressed at their centres. By the eighth day the vesicles are large, sharply defined, and their inflammatory areolæ are confluent. From this time the contents become increasingly cloudy. The vesicles attain their full size by the twelfth day and collapse. By the tenth or twelfth day a brownish scab is forming. This after a time separates, leaving a depressed and pitted or foveated scar which at first is livid, but in course of time becomes dull white in colour.

Headache, malaise and fever accompany maturation of the vesicles at the beginning of the second week; the axillary glands may become enlarged and tender and the spleen palpable. Sometimes febrile disturbance is noticed as early as the fourth day.

In revaccination, the events are similar, but both the local and constitutional disturbances are less pronounced; sometimes they fail to appear at

all. The lesions may run a very rapid course, aborting at the papular or early vesicular stage. Sometimes a slight itching and glandular tenderness are all that is observed.

Natural insusceptibility to primary vaccination is excessively rare, and at least ~~three successive attempts~~ should be made before insusceptibility is assumed.

Although infants can be vaccinated successfully in the first few weeks of life, under ordinary circumstances the best period is from the second to the sixth month. Revaccination is advisable after the seventh year, and when small-pox is epidemic.

The degree of protection afforded against small-pox is in some degree proportional to the extent of the vaccinal lesion, and the resulting scars should, together, cover an area of not less than half a square inch. Hence the advice always to make at least two insertions and preferably four. The test of a successful scar is its depression and foveation. The period of immunity may be regarded as not less than 7 years.

RISKS OF VACCINATION.—Fugitive erythemata, which are sometimes scarlatiniform, measles or urticarial, may appear about a week after vaccination; they resemble serum rashes. Erysipelas, septic infection and cellulitis sometimes result from the use of contaminated lymph or the lack of proper cleanliness at the operation or after. Under modern methods of glycerinisation and asepsis, these should not occur. There is no doubt, too, that syphilis has on rare occasions been conveyed by arm-to-arm vaccination. In such cases, the chancre does not appear before the fifteenth day, and is usually later. The calf being insusceptible to syphilis, the use of calf lymph has abolished this danger. Tetanus is another infection which has occasionally resulted, especially in hot climates. Tuberculosis and leprosy have also been cited as possible sequels, but with little or no proof. The addition of glycerine to the lymph kills the tubercle bacilli. The appearance of eczema and impetigo has been attributed to vaccination, as also a somewhat persistent form of anemia. A rare sequel, to which attention has been drawn recently, is a form of encephalo-myelitis. It sets in 7 to 12 days after vaccination, with headache, vomiting and paresis. These symptoms become aggravated, and delirium may pass into coma and death, but recovery is possible. In other cases the symptoms are more suggestive of meningitis, tetanus, or lethargic encephalitis, with ocular palsies.

Quiescent infection may be brought into activity and prominence by vaccination; this is the case with congenital syphilis and tuberculosis. Hence the advisability of postponing vaccination should the infant show signs of malnutrition or ill-health.

Very rarely the course of vaccinia is characterised by the appearance of a generalised vesicular eruption, the lesions appearing in successive crops, and passing through the stages of papule, vesicle and crust. *Generalised vaccinia* of this type is usually febrile.

Accidental vaccinia is the term applied to fortuitous inoculation from a vaccinal lesion. Mothers are sometimes thus inoculated from their infants. The condition should be borne in mind. When occurring on the face, there is much oedema with swelling of the lymph glands, so that anthrax has been suspected. The vaccinated baby may also, by scratching, inoculate its own nose, cheeks or other parts of its body.

PROTECTION AFFORDED BY VACCINATION.—The immunity to small-pox which vaccination confers is not necessarily permanent. A child vaccinated in infancy should be revaccinated at the age of 7 years and again in adult life. Whatever their vaccinal condition, with the possible exception of those vaccinated within 2 years, persons coming into contact with small-pox should be revaccinated at once.

Since vaccinia has a shorter incubation period than small-pox, a person successfully vaccinated or revaccinated within 3 days of exposure to the latter disease will, in all probability, escape it. Ricketts makes the following statement: "The period of incubation of small-pox, counting to the outcrop of the rash, may be taken as 14 days. If this period be divided into three intervals comprising 7 days, 3 days and 4 days, it will be accurate, in the main, to say that a successful vaccination done in the first period will wholly prevent the attack, done in the second will have more or less effect in modifying the eruption, and done in the third, will merely add to the patient's troubles."

For a discussion of the evidence in favour of the practice of vaccination in the prevention of small-pox, the student is referred to the larger treatises.

CHICKEN-POX

Synonyms.—Varicella; Glass-pock; Water-pock.

Definition.—An acute infective disease, characterised by a rash which tends to appear in successive crops, each lesion passing rapidly through a papular stage to one of superficial vesiculation and subsequent partial pustulation. The lesions then desiccate and scab.

Ætiology.—Chicken-pox is universally prevalent and highly infectious. One attack usually affords complete protection, second attacks being extremely rare. It is mainly an affection of middle childhood, being uncommon after 10 years of age, but adults may contract it, and infants are not completely immune. Season and climate are not known to exert any influence on its incidence. It affects both sexes. Infection is in most cases direct, but articles of clothing may remain infectious for a considerable time, and the disease is sometimes carried by a healthy intermediary. The dried scabs can communicate the disease, probably by ingestion or inhalation. Like small-pox, chicken-pox is inoculable from the vesicles—but not easily. Convalescents from acute diseases, particularly from measles, diphtheria and scarlet fever, are believed to be peculiarly susceptible to chicken-pox. The disease occurs sporadically or in the form of limited outbreaks. The infective agent is unknown.

Pathology.—Micro-organisms occur in the pocks, and protozoon-like bodies have been described similar to those seen in vaccinia and small-pox. The inflammatory lesions are more superficially situated in the skin than those of small-pox; but the process of vesiculation is similar. Loculation is indistinct, and umbilication exceptional. When the clear vesicles become clouded, but rarely before this, polynuclear and mononuclear cells are found in their contents.

Symptoms.—*Incubation period.*—This is usually a fortnight or a little more; but extremes of 11 to 23 days are mentioned.

In childhood the appearance of the eruption usually constitutes the first

sign, and is taken to indicate the first day of the disease. In adults slight pyrexia and sometimes headache, shivering, and even pain in the back may precede the eruption for 48 hours. In exceptional cases, mostly in children, vomiting and convulsions have occurred.

Prodromal rashes are not very uncommon. A patchy or uniform bright red erythema, which may be punctate, sometimes precedes the eruption for some hours, and may be mistaken for scarlet fever; it avoids the face. Much less frequently the prodromal rashes are measly or urticarial in appearance.

The eruption of chicken-pox appears first on the trunk, but soon invades the face, the scalp and the proximal parts of the limbs. Sometimes it is on the face that it is first noticed. Occasionally the eruption invades the mucous membranes, especially the fauces, soft palate and the pharynx. The spread of the rash does not conform to the orderly progress of small-pox, it appears in several crops on successive days; these may come out for 2 or 3 days in mild cases, for a week or more in those which are severe. The total number of lesions may be anything from a few to some hundreds. They are thickest on the trunk, especially on the back, and next to this on the face and in the scalp. They tend to invade the limbs from above downwards, being sparse and often small on the distal portions; a few vesicles are occasionally seen on the palms and soles. The axilla does not escape as in small-pox, and it is unusual for the rash to show an especial incidence over ridges, pressure points or irritated areas.

The lesions are in turn macular, papular, vesicular and mildly pustular. The macules are very transitory, soon becoming rounded or ovoid papules of a pinkish colour and slightly salient, something like the rose spots of typhoid, or larger. Vesiculation rapidly ensues, and is complete in 24 hours or a little more. The vesicles seldom exceed a third of an inch in diameter. They look like translucent droplets, lying on rather than in the skin. An areola may or may not be present. On the scalp, forearms, hands and feet they may appear deeper, and show some hardness. Some assume oval or irregular outlines, especially when lying near creases or folds of the skin. On maturity the vesicles assume a pearly hue. When punctured, most of them collapse entirely, and umbilication is rare. Confluence of adjacent vesicles hardly ever occurs. Owing to its itchiness, the rash is often infected by scratching or rubbing, and then the lesions become larger and more inflamed. Otherwise the vesicles dry up into superficial brown scabs in a day or two, which on separating leave slight pink stains, but no appreciable pitting.

The appearance of the eruption in successive crops leads to the presence at the same time on a given area of skin of lesions in all stages of development, i.e. papules, vesicles, small pustules and scabs. On mucous membranes the vesicles soon rupture and leave shallow grey ulcers, often with red areolæ.

Slight pyrexia usually accompanies the appearance of the rash. Some cases are apyrexial throughout. Rarely the temperature rises as high as 103° or 104° F. Successive crops of spots may be accompanied by successive exacerbations of fever. Constitutional symptoms as a rule are absent.

Varieties.—Chicken-pox varies much in intensity. It may be so mild that only one or two pocks are recognised. As mentioned above, sharp invasive symptoms may mark its advent in the adult. There are three special varieties of the severe disease: (1) *Varicella bullosa*; (2) *Varicella gangrenosa*;

and (3) *Varicella hæmorrhagica*. In *V. bullosa* the vesicles rapidly form large blebs, which on rupture leave painful raw surfaces. *V. gangrenosa* is seen in debilitated children and those recovering from scarlet fever; large dark crusts form, and on separation reveal unhealthy ulcers which may spread on the surface and in depth with great rapidity. Constitutional disturbance is severe, and pulmonary complications often supervene. *V. hæmorrhagica* is rare; hæmorrhages occur into the vesicles and intervening skin, and bleeding sets in from the mucous membranes.

Complications.—Slight bronchitis is present in some cases. Laryngitis may occur, but is rare. Pocks on the conjunctivæ, vulva or prepuce may give rise to troublesome symptoms. Accidental septic rashes sometimes appear in the eruptive stage. Nervous complications have at times been observed, amongst them encephalitis, poliomyelitis, peripheral neuritis, papillœdema, convulsions and chorea. Exceptionally, an acute nephritis appears in the second week, and sometimes an arthritis.

Herpes zoster seems to be in some way connected with chicken-pox. Rarely an eruption of herpes is, sometimes within 24 hours, followed by the rash of chicken-pox. In other cases an eruption, from its distribution diagnosed as herpes, has given rise in contacts, after an incubation period of from 12 to 21 days, to undoubted chicken-pox.

Diagnosis.—The chief diagnostic difficulty which arises is in connection with small-pox. A mild or modified case of small-pox may erroneously be supposed to be chicken-pox, or chicken-pox with a profuse eruption and constitutional, or the rare hæmorrhagic, symptoms may be supposed to be small-pox. The differential diagnosis, in which the distribution of the rash is of primary importance, is considered in the article on small-pox. Here it may be stated that in a patient under 10 years of age, with well-foveated vaccination scars, a profuse eruption is generally chicken-pox, whilst a scanty eruption with well-marked invasive symptoms is more likely in these circumstances to be modified small-pox.

The erythematous prodromal rash may simulate scarlet fever; but the other signs of this disease are wanting, and the chicken-pox eruption appears within 24 hours. Acneiform eruptions on the trunk are distinguished by their distribution, the absence of successive crops and by chronicity.

The crusts of impetigo, when they appear on the trunk, as well as on the exposed parts, may be a cause of great difficulty. The history and duration, as well as the distribution of the lesions, will help.

Pemphigus, which has large bullæ; dermatitis herpetiformis, which is very apt to be recurrent or relapsing, with multifiform lesions both on skin and mucous membranes; and herpes zoster, which on rare occasions is said to be accompanied by a generalised eruption of superficial vesicles, may all give rise to uncertainty.

A varicella-like type of *Lymphilide* is known. It has not the same distribution as chicken-pox, it usually affects the trunk, is much more persistent, and is accompanied by other evidence of its nature.

Prognosis.—Death is very rare. The gangrenous form may prove fatal to debilitated or tuberculous children, and the rare hæmorrhagic form is said by most authorities to have a very bad prognosis.

Treatment.—Although most infectious in the pre-eruptive and early eruptive stages, patients should be isolated until every scab has separated

—usually a period of 2 or 3 weeks. They should be confined to bed during the eruptive period. Skin irritation may be allayed by mild dusting powders, and it is sometimes advisable to fix the arms in light splints, so that the lesions may not be scratched and infected. It is rarely necessary to cut off the hair. Inflamed pocks may need fomentation with boric acid. Crusts which re-form may be removed by starch poultices and zinc or mercurial ointment applied. During the febrile stage light diet is advisable. Gangrenous varicella may be treated by prolonged immersion in a warm bath followed by the application of lotio hydrarg. perchlor. (1 in 2000) to the lesions. A liberal diet with tonics and stimulants is necessary.

When discharging patients particular attention should be paid to the scalp, as scabs may remain entangled in the hair. It is doubtful if lesions which have crusted several times are still infectious. The quarantine period for contacts is 3 weeks.

TYPHUS FEVER

Synonyms.—Jail Fever; Camp Fever; Ship Fever; Typhus Exanthemicus.

Definition.—A highly contagious fever characterised by sudden onset, severe prostration, a characteristic rash, and termination by crisis about the fourteenth day. The infection is conveyed by body lice, perhaps through their bites, but more probably by cutaneous inoculation of their excreta by scratching. Head lice and certain ticks are also believed to be possible vectors of the disease.

Ætiology.—Most of the factors which conduce to the spread of typhus operate by their influence on the parasites by which the disease is conveyed. The lice pass directly from the sick to the healthy, or by means of garments, bedclothes, and mattresses which have been in contact with those infected. Crowding of the sick together in dark, ill-ventilated rooms greatly favours the possibility of infection, whilst in the presence of free ventilation very close contact is necessary before the disease is contracted.

Exhalations from the lungs, emanations from the skin and the excreta are believed to be capable of conveying the infection, and the bodies of those dead of the disease have been supposed to retain their infective powers until decomposition sets in. These beliefs, in view of the part played by lice, obviously need revision. Typhus carriers are always verminous persons. Clothes which harbour infected lice have often transmitted the disease to distant parts.

Typhus is a disease of cold and temperate climates; it occurs in those months of the year when confinement within doors and overcrowding are most likely. In the tropics it is uncommon. In hot climates frequent bathing, scantiness of attire, free action of the skin, and the inimical effect of high temperatures on lice are all factors which prevent the spread of the disease.

Predisposing causes are verminous infestation, overcrowding, and destitution. Typhus is a disease of crowded insanitary towns, prisons, barracks and camps. Epidemics are particularly liable to occur in times of war and famine. Misery, bodily fatigue, alcoholism and fear also predispose to the

infection. Typhus is rare in England, but endemic foci still persist in Irish and perhaps some Scottish towns. In Russia and Eastern Europe the disease is very prevalent, and a great epidemic ravaged Serbia in the early days of the Great War. It has also been recognised in Canada, New York (Brill's disease), Mexico (where it is known as Tabardillo), Manchuria and other places.

Typhus attacks persons of all ages and both sexes. The greatest mortality is in those above middle age (at 50 years it may be 50 per cent., and between 75 and 80 years, nearly 85 per cent.); attacks in the young are less severe and very much less fatal. In populations where the disease is endemic attacks may be very mild, but when introduced into other places the type may prove excessively severe.

Pathology.—The post-mortem appearances are those common to many acute infections and are not in themselves characteristic. Decomposition is early and rigor mortis of short duration. Livid patches and petechial spots are evident in the skin. The viscera are passively congested, and the blood remains fluid. The heart is soft, and its muscle fibres granular. The liver, kidneys and other parenchymatous organs show cloudy swelling. Hypostatic congestion of the lungs and catarrh of the air-passages are common. The absence of characteristic lesions in the bowel affords a distinction from typhoid fever. Beyond occasional meningeal congestion the central nervous system appears normal. Zenker's degeneration may be found in the voluntary muscles, as in typhoid.

Microscopical examination reveals the presence of nodules of endothelial proliferation in the small arteries of the skin and of the brain, also in those of the muscles and viscera.

Of late, much importance has been attached to the discovery of *Rickettsia* bodies (*Rickettsia prowazeki*). These are small and bacilliform, not more than 2 by 0.3 μ in size. They stain pink by Giemsa's stain, often only at their poles. *Rickettsia* bodies are found sparingly in the blood taken from a patient on the seventh to the twelfth day of the disease, and also in infected lice and their excreta. Similar bodies have been described in the vascular lesions and in the endothelial cells of the liver.

An agglutinative phenomenon which goes by the name of the Weil-Felix reaction affords a valuable means of recognising the disease. The reaction is named after two observers who discovered in the urine of patients suffering from typhus an organism of the *Proteus* group which is agglutinated in high dilution by the serum of those infected. The strain of *Proteus* concerned is known as X 19, and agglutinations have been obtained with dilutions of serum up to 1 in 30,000. Reactions in controls, if occurring at all, do not take place in dilutions exceeding 1 in 50. In half the cases of typhus the reaction is found by the fifth day, and in practically all by the tenth day. There is, however, no experimental proof that *Proteus* X 19 is capable of producing typhus, nor does it confer immunity to the disease. It has been pointed out recently that there are at least two varieties of *Proteus* X 19, and that some sera react to one strain and some to the other.

The Wassermann reaction is almost always positive in typhus if the blood is examined before the crisis, but becomes negative again in convalescence (Bauer).

Symptoms.—The incubation period in most cases is about 12 days.

Eight to 10 days is a common interval when the disease is produced experimentally.

The onset is generally sudden. Distressing headache, giddiness, shivering or rigor, and frequently vomiting, mark the accession. Pains in the limbs and back may be severe, and blunting of the mental faculties with great muscular prostration is evident from the first. The tongue is large and coated, but soon becomes brown, and finally may be dark and shrivelled. Appetite is lost, thirst is great, the bowels are generally constipated, and the urine high coloured and scanty, rich in urea and uric acid, but deficient in chlorides. Albumin may appear later and the diazo-reaction is very constant. The face is flushed or dusky, the features swollen and the appearance apathetic. The conjunctivæ are injected and the pupils contracted.

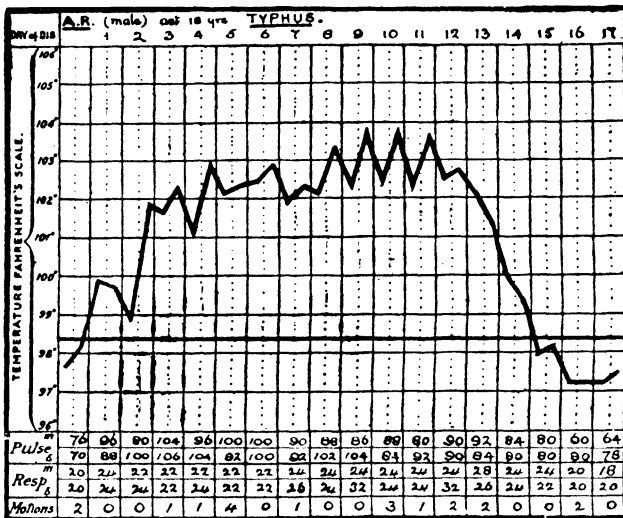

FIG. 5.—Typhus fever. Illustrating a somewhat gradual onset and abrupt termination by crisis.

Epistaxis may occur. The spleen may be palpable, but the abdomen is not distended. Even early in the disease, especially in alcoholic subjects, marked delirium, mania or stupor may be evident. Insomnia is present, or bad dreams disturb the rest. Tinnitus occurs, or deafness of nervous origin. The tongue is tremulous, and the gait tottering; if the patient have not already taken to his bed he usually does so by the third day of illness. The temperature may reach 104° F. by the first night; the acme, however, is generally attained on the third or fourth day. Associated with the fever is a rapid soft pulse. Marked rapidity of the respirations is also noticeable and may lead to an erroneous diagnosis of pneumonia.

The fever (Fig. 5), which during the invasive stage may show remissions, after attaining its maximum, which may be as high as 105° or 106° F., shows little or no daily variation. At the end of the first week or a day or two later a sudden remission, which is rarely lasting, may occur (pseudo-crisis); from

this period, however, the fever generally shows some abatement and terminates by a sudden or somewhat gradual crisis on the thirteenth to the seventeenth day of the disease.

The rash appears on the fourth or fifth day, first on the axillary folds, the sides of the chest and the abdomen. It avoids the face, which is merely flushed and congested, and does not appear on the palate, but with these exceptions it may become general all over the body, although it is most profuse on the trunk, especially on the back. The three elements of which it consists are papules, macules, and petechiæ. The papules resemble the rose spots of typhoid, being small, raised and pink in colour. At first they fade on pressure, later they become dull red or brown and indelible. They do not appear in successive crops. The macular elements of the rash generally appear before the papular elements and are much larger and blotchy; they appear to be in the skin rather than on it, hence the term subcuticular mottling which is applied to the appearance produced. The macules are best seen about the shoulders and axillæ, but often extend to the back and front of the chest, the thighs and arms. Purple petechiæ which resemble flea-bites and sometimes also purpuric patches are less constant. The latter indicate a severe infection, the hæmorrhagic character of which may be confirmed by the occurrence of hæmatemesis, melæna or hæmaturia. Profusion of the rash in typhus is an indication of a severe attack. In mild cases the eruption is scanty, and in children it is very evanescent. Leucocytosis is the rule, the chief increase being in the polynuclear cells.

The cerebro-spinal fluid may show a slight lymphocytosis, and also give a low positive Weil-Felix reaction. The globulin is increased.

About the end of the second week the patient may be considered to enter on the second stage of his disease. There is less complaint of headache; delirium, if present, is less violent and of a muttering rather than maniacal type. Prostration may be extreme and sleeplessness pronounced. The face is dusky, sordes accumulate on the teeth, and a curious mousy odour emanates from the patient. Day by day the nervous depression increases and the patient lies helpless on his back with a tendency to sink down in the bed. The pupils are contracted, the eyes half open and fixed (*coma vigil*). Although deaf and unnoticing, he mutters incoherently and can be roused with some difficulty. Tremors of the tongue and tendons, and picking at the bedclothes are apt to occur. The pulse quickens and may reach 130 per minute. It is dicrotic or almost imperceptible. The heart's impulse is feeble and the first sound faint or inaudible. The blood-pressure falls steadily. Acceleration of respiration is more than ever pronounced, 40 per minute not being unusual; the breathing is shallow, and hypostatic congestion of the lung bases occurs. The urine may be retained or passed into the bed, as also the fæces. Bed-sores are apt to form. The patient may pass away in coma from sheer exhaustion, or hyperpyrexia may precede death.

On the fourteenth day, sometimes a little earlier, sometimes later, the crisis should occur. The condition suddenly improves; the temperature falls, sometimes abruptly, perhaps more frequently by a crisis which is a little more gradual. Sleep ensues and the patient awakes from his stupor with a moist tongue and skin, a clearer intellect and perhaps a slight critical diarrhœa. Inclination for food returns, but there is still extreme weakness. Some, failing to rally after the crisis, fall into a state of collapse. In less

severe cases, where the typhoid state has not been pronounced, the crisis may occur rather earlier and recovery be much more rapid; this is especially the case with children.

Varieties.—Typhus may occur in forms which are characterised by extreme mildness or by fulminant severity. The milder types are particularly seen among the natives of localities where the disease is endemic, and in children. Of the severe types, that known as *typhus siderans* or *blasting typhus* is the most striking. In this form death may occur within 2 or 3 days of the onset. A meningeal variety, accompanied by head retraction, ptosis, squint and other nervous symptoms, simulates meningitis. Some cases are characterised by fierce maniacal delirium. Typhus also may assume a hæmorrhagic form, but this is uncommon. Relapse in typhus is almost unknown, and authentic second attacks are excessively rare.

Complications and Sequelæ.—Respiratory complications in the form of bronchitis, broncho-pneumonia, or hypostatic congestion of the lungs are the commonest. Rarely laryngitis occurs and may lead to necrosis of the cartilages and œdema of the glottis. True lobar pneumonia is hardly ever seen. Diarrhœa is sometimes troublesome; it may be accompanied by abdominal distension and the passage of blood. Femoral thrombosis, analogous to that of typhoid fever, is common. Sometimes arterial occlusion occurs, leading to gangrene of the extremities. Septic or gangrenous infarcts may be formed in the lungs by emboli detached from clots in the heart or the vessels. Suppurative parotitis is a rather marked feature of the disease, and the inflamed gland may become gangrenous. Gangrenous bed-sores, too, are apt to form with great rapidity and pyæmic complications may ensue. When typhus is followed by hemiplegia or other forms of paralysis, thrombosis or embolism of cerebral arteries should be suspected. Mania, melancholia and dementia are occasional sequels but generally clear up, although they may take several months to do so. Amongst rarer complications may be mentioned nephritis, cystitis, orchitis and jaundice.

Diagnosis.—As compared with *typhoid*, the onset is more sudden, and prostration is earlier and more pronounced. The aspect is drunken, the face congested, the pupils contracted and the eyes suffused. Diarrhœa and abdominal symptoms are unusual. The eruption is more profuse and more widely distributed, and the spots, which are paler than those of typhoid, are accompanied by subcuticular mottling. The termination of the fever is more abrupt. Blood cultures and agglutination tests are of great value in distinguishing the two diseases, and to those acquainted with typhus the peculiar mousy odour, which is absent in typhoid, is of assistance. *Lobar pneumonia*, especially the apical form with slight meningeal symptoms, may be mistaken for typhus, but should be eliminated by careful and repeated physical examination of the lungs. The hypostatic pneumonia of typhus is bilateral and does not show frank signs of consolidation. Herpes may occur in both diseases. *Meningitis* is now easily distinguished by lumbar puncture and examination of the cerebro-spinal fluid. *Encephalitis lethargica*, with fever, headache and delirium, must be distinguished by the absence of the characteristic rash of typhus, the negative Weil-Felix reaction, and the supervention of such signs as ptosis, ophthalmoplegia, and characteristic lethargy from which the patient can be roused. The cerebro-spinal fluid may show a lymphocytosis, without globulin increase, or it may contain

blood. *Uræmia* is sometimes confused with typhus, but is distinguished by the absence of fever and rash and the condition of the urine. Difficulty occasionally arises with a fading *measles* rash, but unlike the rash of typhus this invades the face. A history of catarrhal symptoms may also be obtained in measles. The *spotted fever of the Rocky Mountains* closely resembles typhus. In hot climates and on campaigns other possible sources of error in diagnosis are small-pox, relapsing fever (epidemics of which often coincide with those of typhus), sandfly fever, and malaria. Influenza also may lead to difficulty.

Prognosis.—The mortality, which is low in childhood and adolescence then progressively increases, reaching 35 per cent. between the ages of 35 and 40. In aged patients, recovery is the exception. Clinical indications of gravity are persistent sleeplessness, marked subsultus, violent delirium or convulsions, evidence of a hæmorrhagic tendency, a profuse petechial rash and continued high fever or hyperpyrexia. Failing circulation is shown by lividity, coldness of the extremities and hypostatic congestion of the lungs. Suppression of urine and uræmic symptoms are also of grave import, as also are gangrenous bed-sores, extensive parotid suppuration and pyæmic symptoms. The disease is particularly deadly to alcoholics, and fat subjects are much less resistant than the thin.

Treatment.—*Prophylactic.*—Every effort should be made to get rid of lice. The patient should be stripped, the hair clipped short, and the body shaved and thoroughly washed before admission to a ward. The garments of attendants should be so arranged as to prevent as far as possible the risk of being bitten. The clothing of those infected, and of contacts, should at once be adequately sterilised and their living rooms and their contents disinfected. Cases of typhus are best treated in isolation hospitals, and when the disease is epidemic good results are obtained by forbidding movements of the populace in the infected areas.

A quarantine of immediate contacts for at least 15 days is usually recommended.

The *general* treatment should be on the same lines as those adopted in typhoid fever. Free ventilation, tepid sponging night and morning, careful attention to the mouth and back, and the adoption of a fluid diet, consisting of milk, beef tea, meat extracts, and plenty of water, are the essentials. The bowels are usually constipated and enemas should be used. The bladder should be watched; retention of urine may lead to great restlessness and constant overflow. When the temperature rises above 103° or 104° F., tepid or cold sponging should be repeated. In hot climates, exposure to undue heat has a very deleterious effect. For sleeplessness, paraldehyde is the most useful hypnotic, but requires to be given in large doses. Wildly delirious patients need some form of restraint, and in these cases hyoscine should be tried if other means fail. Frequent rectal salines or the administration of saline solution intravenously or subcutaneously are beneficial when toxæmia is extreme. For venous thrombosis the intravenous administration of 1 per cent. sodium citrate in saline solution and the use of sodium citrate by the mouth is recommended. The tendency to collapse after the crisis should be remembered, and patients carefully watched at this period. For further details of symptomatic treatment the article on typhoid may be consulted.

MUMPS

Synonyms.—Epidemic Parotitis ; Infectious Parotitis.

Definition.—An acute infectious disease, characterised by swelling of the parotid, and sometimes of the other salivary glands, accompanied by constitutional disturbance which is usually mild. With the exception of orchitis, complications are infrequent, and a fatal termination is exceedingly rare.

Ætiology.—Mumps is widely distributed, being endemic in most large centres of population throughout the civilised world. No climate is adverse, and no race is known to be immune. Children and young adults of both sexes are those usually attacked ; but no age is entirely exempt, although the disease is rare in infants and in the aged. The mother has transmitted the disease to the foetus *in utero*.

The malady usually appears during the winter or spring months. Outbreaks are generally localised, and often limited to particular schools, business houses or barracks. Infection is direct from patient to patient ; but is sometimes conveyed by an apparently healthy intermediary, or by fomites. Epidemics of mumps may follow outbreaks of measles.

Pathology.—From analogy with other specific infections, mumps is attributed to a microbic invasion ; but the organism has not as yet been positively identified. Several observers have found a Gram-negative diplococcus in the blood, secretions, and fluid obtained by gland puncture ; but final proof that it is the cause of the disease is not yet forthcoming.

It is assumed that the affected salivary glands are invaded by way of their ducts. Opportunities for histological examination are rare ; but a striking feature appears to be the predominance of interstitial and periglandular rather than parenchymatous inflammation. In the case of the testicle, atrophy is said to result from a parenchymatous rather than from an interstitial inflammation, the basement membranes of the seminal tubules becoming thickened and their epithelium atrophic. An examination of an enlarged pancreas from a case of mumps is reported to have shown hypertrophy of the glandular acini with commencing cellular degeneration.

Symptoms.—The incubation period is 3 weeks ; but extremes of 14 and 25 days, or even one month, are admitted. A swelling of the parotid gland is usually the first indication of the malady, but this may be preceded for a short time by pain and stiffness in the lower jaw, or by such prodromal symptoms as feverishness, shivering, sore throat, headache, earache, drowsiness and even vomiting.

The parotid swelling is at first unilateral, and more commonly appears on the left side. It may continue to increase for 2 or 3 days, forming an ill-defined, elastic swelling, which obliterates the sulcus between the mandible and the mastoid process, lifts the auricle away from the head in a characteristic manner, and extends forwards on the surface of the masseter. Only rarely is the skin over the gland either reddened or oedematous. The swelling slowly subsides after a few days, sometimes very quickly, but a distinctive and, when present, highly diagnostic feature is the occurrence, 24 or 36 hours after onset, of swelling in the other parotid region, sometimes with fresh febrile disturbance ; or the submandibular and sublingual glands may be attacked. The interval between the invasion of the two parotid glands

may extend to 4 or 5 days, or even longer; but sometimes they are attacked simultaneously. Sometimes, too, the submandibular glands become swollen first, in which case the parotid may escape evident implication, or may swell in its turn. When bilateral glandular swellings are present the features become much distorted.

Moderate pyrexia (101° or 102° F.) may accompany the onset of mumps and persist for a day or two; but the attack is often afebrile and the pulse rate hardly quickened. On rare occasions constitutional disturbance is severe, the temperature rising to 104° or 105° F., with delirium and circulatory depression.

The swollen parotid gland may by its tenderness cause great pain on attempts to separate the teeth, to chew or to swallow. The secretion of saliva is often defective, but in some excessive salivation is noticeable. Injection of the orifices of the salivary ducts, pharyngitis, faucial congestion and even tonsillitis are sometimes observed at the height of the attack; but it may be very difficult to separate the jaws sufficiently to inspect the throat. Enlargement of the cervical lymph glands may accompany the parotid swelling. Mumps may appear in so mild a form as to be hardly noticeable. Rarely the only salivary gland affected is the submandibular (submaxillary mumps), and occasionally orchitis is the sole manifestation of the disease.

With rare exceptions the glandular swellings caused by mumps neither suppurate nor persist, although, occasionally, the parotid swelling is said to be several months in resolving.

Complications.—*Orchitis* is a well-known sequel which occurs in 15 to 30 per cent. of the cases. It tends to affect boys about the age of puberty and young male adults; in childhood it is rare. The seventh or eighth day of illness is the usual time of onset; but it may appear 2 or 3 weeks later, and is sometimes longer delayed. In some instances orchitis precedes the inflammation of the salivary glands. The onset is characterised by pain in the testis, which soon becomes swollen. The swelling is tender and elastic. Effusion in the tunica vaginalis may occur; the epididymis is not often involved. Abdominal rather than testicular pain is sometimes the first sign. Severe constitutional symptoms such as delirium, vomiting, collapse and considerable fever may accompany the testicular inflammation. The temperature may rise abruptly to 103° or 104° F. Fortunately the complication is usually one-sided. It may be accompanied by redness and œdema of the scrotum, swelling of the spermatic cord and enlargement of the inguinal glands. Exceptionally a urethritis, which is not gonorrhœal, accompanies the testicular swelling. Subsidence of the orchitis within a week is the rule, the temperature, if raised, falling rather abruptly. Suppuration is very rare; but relapse sometimes occurs. Atrophy of the testis is a sequel to be expected. When bilateral orchitis occurs before puberty the development of the individual is usually checked; but even when both testes appear atrophic sexual vigour may be retained (Osler).

In the female, corresponding complications are ovaritis, shown by ovarian pain and tenderness, inflammation and œdema of the vulva and mastitis. The latter has also occurred in the male.

Pancreatitis is a much less common complication than orchitis; it is said, however, to be a special feature of some epidemics. It should be suspected when acute abdominal pain, accompanied by vomiting and epigastric tender-

ness, occur as sequels to the parotid swelling, which under these circumstances may show a rapid subsidence. Sometimes the swollen pancreas may be felt, but often its presence is masked by abdominal rigidity. The bowels are constipated, the stools may be fatty, or even contain blood. Sometimes hæmatemesis occurs. The urine may contain sugar. Jaundice is rare. Fever and acceleration of pulse are to be expected. The onset may be accompanied by alarming collapse. Fortunately recovery has occurred in most cases.

During the course of mumps the lachrymal gland sometimes becomes swollen. In such cases orbital pain is complained of, and the eyelids become swollen. In other cases thyroiditis has been observed.

As regards the *nervous system*, meningeal symptoms, headache, photophobia, delirium and rigidity of the neck have supervened in more than a few instances. Sometimes on recovery such symptoms as aphasia, hemiplegia, monoplegia or ataxia persist; they are suggestive of the occurrence of encephalitis, or of some vascular lesion in the brain. Rarely a general paralysis of the limbs with loss of deep reflexes, attributed to peripheral neuritis, occurs. Weakness of the muscles supplied by one facial nerve sometimes accompanies the parotid swelling, sometimes succeeds it.

An excess of lymphocytes may be found in the cerebro-spinal fluid.

Acute mania and other forms of insanity are rare sequels.

Certain affections of the *organs of special sense*, although uncommon, deserve mention on account of their importance. Quite apart from deafness, due to the occasional occurrence of otitis media, true *nerve deafness* may occur unaccompanied by signs of middle ear disease. The deafness is of sudden onset, and when accompanied by nausea, vomiting, tinnitus and inco-ordination it is attributed to hæmorrhage or exudation within the *labyrinth*; but it may occur without any labyrinthine symptoms. Fortunately the deafness is usually unilateral, for it is incurable.

Papilloedema and optic atrophy with loss of vision are other important sequels. Iridocyclitis, paralysis of certain extra-ocular muscles and loss of power of accommodation may also at times ensue; these mainly terminate in recovery after a variable time.

Among other possible complications may be mentioned epistaxis, bronchitis, pneumonia, pericarditis, *arthritis and nephritis*. The arthritis resembles that of gonorrhœa or scarlet fever, rather than acute rheumatism. Nephritis sometimes occurs as late as 4 or 5 weeks after the salivary swellings; uræmia has been responsible for death in rare instances.

Suppuration in the parotid gland, gangrene of the gland, cellulitis of the neck and floor of the mouth, oedema of the glottis, and suppuration of the cervical lymph glands are very rare occurrences, which are generally attributed to superadded septic infection. Relapses, characterised by a recurrence of the glandular swelling after a distinct interval, are not very uncommon. Although one attack of mumps usually protects the individual for life, second attacks are not unknown.

Diagnosis.—In the presence of an epidemic this presents little or no difficulty; but the true nature of the infection may be overlooked when the parotid swelling is insignificant, or when the disease primarily affects the submandibular or sublingual glands, or again when orchitis or even pancreatitis constitutes the first symptom.

Parotitis, usually unilateral, and attributed to ascending duct infection from a dry and dirty mouth, is a well-known complication of certain fevers of the enteric group, and of some abdominal diseases. This is distinguished from mumps by the circumstances under which it occurs, and by the fact that it is not contagious. It generally ends in suppuration. It is well to bear in mind that swelling of the salivary glands may follow the administration of certain drugs, such as iodide of potassium and pilocarpine.

A painless enlargement of the parotid and lachrymal glands, characterised by great chronicity, occurs in Mikulicz's disease.

Inflammatory swelling of the higher cervical glands, especially when accompanied by peri-adenitis and oedema, may be mistaken for mumps. Swelling of this character occurs in certain cases of diphtheria, and also in scarlet fever. Careful attention to the history, proper examination of the fauces, and search for rashes should eliminate this error. Enlargement of the pre-auricular lymph gland due to lesions about the nostrils and angle of the mouth, and the swelling caused by periostitis of the lower jaw may superficially resemble inflammation of the parotid.

When the submandibular and sublingual glands alone are swollen the distinction from lymphadenitis may be difficult. In such cases extension to the opposite side indicates mumps, as also does the transitory character of the swelling.

In glandular fever, which is an acute infective adenitis of the cervical and other lymphatic glands, the salivary glands are not involved.

Treatment.—Mumps is infectious for 2 or 3 days before the glandular swelling appears, and isolation for not less than 2 weeks from the onset is advisable, provided that 1 clear week has elapsed since the subsidence of the glandular enlargement. Contacts should be isolated for 26 days unless they have previously had the disease. The patient should be isolated and confined to bed. The incidence and severity of orchitis are said to be less in those who are not allowed to get up until the time at which this complication usually appears is past. Foods which are easily swallowed and need no mastication are indicated during the acute stage. The mouth should be kept clean with a mild antiseptic lotion. Pain in the parotid may be relieved by smearing it with glycerine and covering with hot cotton-wool or by fomentations. Acetyl-salicylic acid in 10-grain doses is also of value. The inflamed testicle should be enveloped in cotton-wool, and suspended or supported by a small pillow. Hot applications are also serviceable. If pancreatitis be suspected, fomentations may be applied to the abdomen, small doses of opium administered, and the diet strictly restricted to fluids. In all cases the bowels should be regulated with calomel, followed by a saline or some other aperient. Delirium and pyrexia are met by sponging, wet-packs or the ice-cap; and collapse by warmth, stimulants and strychnine.

GLANDULAR FEVER

Synonym.—Infectious Mononucleosis.

Definition.—An acute infectious disease characterised by fever and rapid enlargement of the anterior cervical lymph glands, and sometimes

also those of other regions. In most cases lymphocytosis occurs. Recovery is the rule.

Ætiology.—The disease occurs in small epidemics, and is infectious, although the infecting organism is unknown. It is a disease of childhood, not often seen in infancy and rare after puberty. Most of the attacks occur in children of school age, and more males than females are affected. The duration of infectivity is probably short.

Symptoms.—The incubation period is about a week, but it may vary from 5 to 12 days. The onset is sudden, with malaise, fever, slight soreness of the throat and, perhaps, slight stiffness of the neck and pain on swallowing. Soon swelling of the lymph glands of the anterior cervical and submandibular groups becomes evident, and increases rapidly. By the second or third day the glands may attain a considerable size. They are discrete and tender, but the skin over them is not inflamed. The swelling at first is unilateral and more commonly appears on the left side, but afterwards the glands on the other side may enlarge in turn, and sometimes minor enlargements of the posterior cervical, axillary, inguinal and epitrochlear glands occur. The adenitis is accompanied by pyrexia, the fever ranging irregularly from 100° to 103° F., or even higher.

The glandular swelling need not be limited to the superficial groups, or even commence in them. Paroxysmal cough, sometimes accompanied by substernal pain and dysphagia, suggests implication of the mediastinal glands, and may precede the cervical swelling. Vomiting and abdominal pain may be accompanied by palpable swelling of the mesenteric glands. In many cases, slight enlargement of the spleen and also of the liver may be detected. Examination of the blood in the acute stage of the disease shows a characteristic increase in number of mononuclear, non-granular cells, which resemble lymphocytes, and the lymphocytes may form from 40 to 80 per cent. of the total leucocytes, instead of the normal 20 per cent. The total leucocyte count is rarely more than 12,000 to 18,000. The red cells are not diminished in number.

The febrile stage of the disease may last for 10 days or longer, and exacerbations of fever, with involvement of fresh glandular groups, may occur. The glandular swellings subside more slowly than the fever. The lymphocytosis may be very transitory, or may persist for some time. Convalescence is slow.

Complications.—These are few. The sore throat is little more than a mild catarrh; sometimes there is exudate on, or actual ulceration of, the tonsils or pharynx. There may occur a slight temporary albuminuria, with a few tube casts, but in some 6 per cent. of the cases a hæmorrhagic nephritis ensues. Suppurative otitis and retropharyngeal abscess have been recorded. Suppuration of the glands is rare.

Diagnosis.—The disease has been mistaken for mumps, scarlet fever, Vincent's angina, acute lymphatic leucæmia, Hodgkin's disease, tuberculous adenitis, and the rare form of tonsillitis known as agranulocytic angina. The clinical course is so characteristic that if this, together with the epidemic prevalence, be borne in mind, no mistake will be made. The salivary glands are not enlarged as in mumps. There is no rash. Vincent's angina may complicate glandular fever, but any leucocytosis is said to be polynuclear, with very rare exceptions. Acute lymphatic leucæmia at its onset

constitutes a very real difficulty, but the leucocytosis is usually far in excess of that of glandular fever, anæmia is progressive, and the issue fatal. Hodgkin's disease is a much more chronic and progressive affection, and lymphocytosis rarely occurs. Tuberculous adenitis also has a greater chronicity, with sooner or later a tendency to periadenitis and perhaps suppuration; and other signs of tuberculosis may be present. Agranulocytic angina, as its name denotes, is characterised by the disappearance of all granular cells from the blood. It usually occurs in middle-aged women, and the prognosis is very bad.

Treatment.—This is purely symptomatic.

CHARLES R. BOX.

RHEUMATIC¹ FEVER

Definition.—An acute, specific disease, characterised by fever, arthritis and a special tendency to endocarditis.

Ætiology.—The essential cause of the disease is unknown. That the *matrices morbi* is microbic there can be very little doubt, and for these reasons: the clinical features of the disease bear a strong resemblance to those seen in diseases of undoubted microbic origin, and especially in septicæmia due to streptococci and to staphylococci; the curves of incidence of the disease rise and fall with the curves of incidence of scarlet fever and of erysipelas; and the disease runs a natural course—or it did prior to the use of salicylates. By some the disease is thought to be a mild form of (streptococcus) pyæmia. Against this view is the fact that the disease is by no means always a mild affair, even when compared with known streptococcus pyæmia; also against the view is the fact that the inflammatory lesions produced, though often very acute, never suppurate; and salicyl preparations have a marked inhibitory action upon the disease-process, whereas their effect in coccus septicæmias is almost nothing.

Others consider the disease to be an intoxication from a local (streptococcus) infection; this conception introduces scarcely fewer difficulties than the former. The bacteriological part of the problem, to which during recent years much attention has been given, remains unsolved.

Poynton and Paine, whose many contributions to this part of the subject and to the pathology of the rheumatic process in general, have been of great importance, claim to have isolated the specific cause of rheumatic fever in the shape of a paired coccus to which they give the name *Micrococcus rheumaticus*. The characters ascribed to this micro-organism have varied somewhat in different descriptions, and Andrewes and Horder pointed out that in its morphological and biochemical features it corresponds with the short streptococci of feeble virulence normally present in the intestine, to which they give the name *S. faecalis*. Poynton and Paine consider that they are able to produce in rabbits, by intravenous injection of their coccus, lesions identical with those seen in rheumatic fever in man. But the comparison must be a very difficult, if not an impossible, one, between lesions so produced and lesions which it is quite easy to produce in this animal by the injection

¹ The word "rheumatic" is used throughout this article to signify conditions strictly belonging, or allied, to rheumatic fever, and not to include either of the many states loosely described as "rheumatism."

of streptococci for which no causative relation to rheumatic fever is claimed. Thus, Cole was able to produce endocarditis and non-suppurative arthritis in rabbits by the injection of streptococci derived from cases of disease obviously not rheumatic fever, and Horder achieved the same result with *S. faecalis* and *S. salivarius*, cultivated from healthy human stools and saliva.

Ainley Walker and Beattie have also isolated cocci from the blood and exudates in rheumatic fever, but the micro-organisms described by them do not appear to be identical with that described by Poynton and Paine.

The crux of the position is the failure of a large number of careful workers to isolate any micro-organism from the blood and joints during life, even in very severe cases of uncomplicated rheumatic fever. This was Cole's experience in Osler's wards; it was Horder's at St. Bartholomew's Hospital; it was Bulloch's at the London Hospital. Horder points out that the significance of this negative result is enhanced by the fact that modern methods of blood and joint culture are on the whole very successful, allowing of the isolation of such delicate micro-organisms as Pfeiffer's bacillus and the gonococcus, whereas the cocci described by Poynton and Paine and others are hardy growers and, therefore, unlikely to elude careful culture if present as a constant association of the disease.

Investigations conducted in the post-mortem room are of little use in evidence on this question, since it is admitted by all workers that in the fatal cases of rheumatic fever available for such purpose, secondary streptococcus infections are not uncommon. Horder draws attention to the necessity of excluding all cases of infective endocarditis as material for bacteriological investigation in respect of rheumatic fever, a warning that is prompted by the fact that Poynton and Paine term such cases "malignant rheumatism" when they follow immediately upon an attack of rheumatic fever.

The omission to make this distinction between infective endocarditis (most often a streptococcus infection of valve segments previously damaged by rheumatic endocarditis) and severe rheumatic fever may account in part for the discrepancy in the results of blood culture by different workers to which reference has already been made. But although evidence is against the view that rheumatic fever is the expression of a streptococcus septicaemia, it is less certain that it is not an intense intoxication from some focus of streptococcus infection, such as the tonsil or the intestine. It is possible that a sudden rise in virulence occurs in cocci lodged in one of these, or in some other situations, and that an auto-intoxication follows without actual blood infection. Acute tonsillitis is certainly common during the period of invasion of the disease, and there are reasons for regarding appendix inflammation as being associated in causative fashion with some cases.

In two or three fatal cases, examined post mortem at St. Bartholomew's Hospital, Mervyn Gordon demonstrated to the writer an enormous quantitative increase in Gram-positive cocci lying in the lymphoid tissue of the lower part of the ileum. But it is possible that such situations are but the channels of entry of a virus as yet unknown, and that the increase in the cocci habitually present in them is of the nature of an epi-phenomenon.

To sum up: The causative agent in rheumatic fever has not as yet been definitely established. Streptococci are frequently associated with the specific lesions post mortem, but have been obtained hitherto only by a few workers during life, and the types of streptococci obtained by them show certain

marked differences in character. It is possible, indeed it is probable, that the causative microbe, if bacterial, is of the nature of those micro-organisms termed ultra-microscopic. The subject requires further work before a solution is forthcoming.

The disease is more common in humid and temperate *climates* than in others; it is probably more common in Great Britain than anywhere else. The *sexes* are affected almost equally, but there is a slight preponderance in males, no doubt owing to their greater tendency to exposure. Rheumatic fever is pre-eminently a disease of pubescents and young adults, but it occurs at all *ages*, though it is uncommon in infants and in the elderly. If a person has had recurring attacks up to the age of 40, he is prone to them afterwards, but otherwise the susceptibility to the disease becomes greatly diminished after the age of 30. It is one of the striking facts of medicine that there are rheumatic families, in whom the tendency to the disease is highly marked. A certain *complexion* is common in them: a clear skin, with fair—often rufous—colouring.

Exposure, fatigue and damp are precipitating causes of the attack: a railway journey in wet clothes after muscular exercise, or sleeping in a damp bed, is a not unusual event in the patient's history of the onset. But it is equally true that many attacks come on in the absence of all these factors; indeed, attacks are not at all infrequent in hot weather. *Autumn* provides more attacks than any other season of the year.

Symptoms.—The onset is usually abrupt, with the sense of *chill*, accompanied almost at once by *pains in the joints*, the *knees* and ankles being the commonest. One or two joints usually precede the rest in order of invasion, to be quickly followed by others: wrists, shoulders, hips, neck, tarsus, metatarso-, and metacarpo-phalangeal joints. Some degree of sore *throat* is very common, and may be a marked feature; when this is so, the *tonsils* usually show the redness and swelling more than other parts. By the end of the second or third day it is usual to find a considerable number of joints affected, so that the patient is already in much pain and great discomfort. The affected joints are swollen and red, and synovial effusions appear, especially in the *knees, wrists and ankles*. There is great variation in the extent and in the *degree* of the joint involvement in different cases. In a few instances less common joints share the inflammation: sterno-clavicular, vertebral, interphalangeal. The *fibrous tissues* suffer as well as the joints, and it is often apparent that this accounts for some, at least, of the stiffness and grave discomfort. The joint effusions never suppurate.

The *temperature* usually rises to 102° to 103° F. with the arthritis and synovial effusions, and the fever remits, or even intermits, so that the chart shows an "irregular" curve. The pyrexia is peculiarly sensitive both to exacerbations in the disease (which are common), to relapses (which are also common) and to complications. Sweating is generally *profuse*, the sweat being of a peculiar "acid" smell. The *urine* is scanty and high coloured, and if the fever is marked there is usually a trace of albumin present; a deposit of *urates*, coloured brick-red by uro-crythrin, is a feature in most severe cases. As in most acute fevers, the *secretions* of the mouth and alimentary tract are lessened, leading to a heavily coated tongue, anorexia and constipation.

The *heart* is generally—some authorities believe always—affected, though the nature and the degree of the affection is variable. There are few, if any,

cases in which careful examination from day to day does not reveal a slight degree of "softness" of the first sound of the heart, due, no doubt, to affection of the myocardium. The pulse is raised moderately in frequency (90 to 120), its volume is good but its tension is reduced. In more cases than not, probably, a soft systolic apex-bruit appears, not necessarily indicating either endocarditis or dilatation. In about half of all cases there are reasons for concluding that acute endocarditis is present, as judged by the character of this bruit, its transmission towards the axilla, some evidence of enlargement of the heart and a rise in the temperature coincident with the appearance of the heart signs. This complication usually arises about the eighth to the tenth day.

The blood shows a considerable leucocytosis (15,000 to 30,000) and an acute "secondary" anæmia which is a constant feature of the disease and quickly reveals itself in the patient's facies.

ABERRANT TYPES.—*Subacute* attacks are common, especially in children (see p. 297) and in old rheumatic subjects. Their importance lies in the fact that all the time the heart may be suffering damage. Although this is less common in adults than in children, arthritic signs may be absent in cases of rheumatic endocarditis, as in rheumatic pericarditis.

Complications.—As already stated, about one-half of all cases develop some form of heart trouble. We have spoken of myocarditis and of acute endocarditis, and of the advent of the latter, should it arrive, about the end of the first week. The endocarditis is generally valvular; most often mitral, less often aortic, but in some cases both mitral and aortic. In a much smaller percentage of cases it is mural, the part of the endocardium then affected being, by choice, the lining of the left auricle. *Pericarditis* is less common; and pericardial effusion, especially of the massive sort, is nowadays quite uncommon. (For full accounts of these important cardiac complications, see special sections.)

Skin eruptions, though a specific feature of the infections, are not very common, except in children. The profuse sweating quite often leads to sudamina, and these, becoming inflamed, lead to miliaria. True rheumatic erythemata are much more common in the subacute cases than in the acute ones. Purpuric eruptions, again, are more often seen in aberrant types of the disease (e.g. Henoch's Purpura and Peliosis Rheumatica).

The only pulmonary complication of any consequence is pleurisy, and this is by no means common if we preserve the usual strict criteria of physical signs for its recognition, and omit "pleurodynia," in which condition the pain is more often intercostal than pleural. Indeed it may be said that, in the absence of pericarditis and of severe endocarditis, rheumatic pleurisy is quite rare. Pneumonia, properly speaking, does not occur, but there is a condition of lung in severe rheumatic fever, again when complicated by grave endocardial, pericardial and pleural affections, which simulates it somewhat. The lung tissue is in a mixed state of congestion, collapse and œdema.

Hyperpyrexia was formerly a much dreaded, and not very uncommon, complication. It is now quite rare. There is, indeed, by some modern observers, doubt thrown upon the rheumatic nature of the cases described under this term. May they, for example, have been fulminating cases of septicæmia or meningitis? It is clear that no case could nowadays be termed rheumatic hyperpyrexia unless lumbar puncture and blood culture

findings were proved to be negative. But the strongest points in favour of regarding some, at least, of the cases as having been rheumatic, and not meningitic or septicæmic, are (1) the very high degree to which the temperature rose (107° to 110° F.); and (2) the fact that in some of the cases, at least, the clinical picture was definitely that of rheumatic fever before the event, and when recovery occurred as the result of prompt treatment it was similar afterwards. The condition arises suddenly in most cases, though in a few there is a suspicious prodromal amelioration in the pain, sweating and general discomfort. The temperature rises rapidly to 106° , and unless checked by cold applications it may quickly reach 109° or 110° F. Before this stage is reached the patient has become tremulous and excited, then delirious and then semi-comatose, with a dusky lividity of the face and a failing pulse. Most of such cases are fatal. If prompt treatment succeeds in lowering the pyrexia it may need to be resorted to again in a few minutes or hours, since recurrence of the condition is to be expected.

Course.—Before the introduction of salicylates the course of rheumatic fever was, in the words of Sir Thomas Watson, “six weeks.” Nowadays it is much shorter; 10 days to 3 weeks, if we include the joint swellings, though the fever is generally over in a shorter period than this when the treatment is prompt and thorough. If residual joint inflammations prolong the course of the disease it is important to look for contributory causes, and especially for septic foci. Recrudescences are very common, especially if full treatment be relaxed too early. Complications necessarily prolong the course of the disease.

Convalescence is often tedious, and the resultant anæmia and heart weakness warn the careful practitioner not to attempt to hurry it. Rheumatic fever patients are as liable to relapses as they are to recrudescences, and it is no uncommon thing to see a patient slip again into almost as bad a state as he originally was, including, it may be, painful swelling of the very same joints as were first affected. The great danger of these relapses lies in the risk of heart inflammations arising during the subsequent attacks, when perchance the patient escaped them at the first.

RHEUMATIC FEVER IN CHILDREN.—The disease is very common in children, in whom, however, the clinical picture as above described is apt to be departed from in several respects. (1) The arthritis is oftentimes a less marked feature; it may be absent altogether, and even when it is a troublesome element in the case, the degree of pain is prone to be disproportionate to the amount of redness and swelling of the joints. (2) Skin eruptions are relatively more common—various erythemata especially, but also purpura. (3) Rheumatic “nodules” are almost confined to children. These are discrete fibrous lumps, varying in size from small peas to horse-beans; they are found in the scalp, along the margins of the scapulæ and bones of the forearm, about the knuckles and elbows, and, less often, in other situations. They are sometimes tender and painful. They come and go. Occasionally they are present in large numbers: the case is then most likely to be subacute in type and very tedious in its course. (4) But the most important difference observable between the disease in children and in adults is the fact that in the former the process is not seldom subacute in its onset and course, and for this reason frequently overlooked for a time. Add to this fact that the tendency to heart involvement in these subacute attacks is no less than in

the more acute and more highly febrile bouts, and it is obvious that the recognition of this state of things is of the utmost importance. Unfortunately a large number of cases of subacute rheumatic endocarditis must needs arise without the possibility of prevention, but it is probable that a large number might also be prevented, or considerably modified, by prompt treatment of the subacute rheumatism in childhood which causes the injury. These attacks of subacute rheumatism are sometimes characterised by intercostal pain, sometimes by abdominal pain, sometimes by pain in the legs without special reference to the joints. There seems no doubt that so-called "growing pains" are often rheumatic in nature. In any child so affected the heart should be examined critically, and from time to time. The presence of sore throat, of acid sweats, of one of the erythemata, in conjunction with the above-named pains, should determine a decision to treat the child as suffering from the rheumatic process. The presence of nodules is decisive in a doubtful case.

Diagnosis.—Cases of the fully developed disease do not often lead to difficulty in diagnosis, given ordinary care on the part of the practitioner. A few diseases, however, require mention. (1) Pyæmia due to coccal infection may lead to some confusion, and the following differential points are worthy of notice. In septicæmia, when there is arthritis, the latter is usually constant in one or two joints, not fugitive and involving many as in rheumatic fever. Moreover, the joint changes tend to supuration and permanent destruction of the joint structures. Blood cultures and joint-puncture fluids are not infrequently positive in pyæmia, whereas they are constantly negative in acute rheumatism. Rigors are common in pyæmia; in rheumatic fever they do not occur. If endocarditis complicates pyæmia, the heart infection is likely to lead to embolism, a condition not found in rheumatic fever.

(2) In children acute osteomyelitis may be mistaken for rheumatism; rarely does the converse error arise. But the disease-process is nearly always much more severe, the temperature being much higher and showing greater oscillations. The painful part is generally the lower end of the femur or tibia, and careful examination reveals it to be epiphyseal rather than arthritic. As in pyæmia, to which type of infection the disease really belongs, blood cultures are usually positive (Staphylococcus aureus).

(3) Gonorrhæal arthritis is not usually so acute a disease, nor is the patient often so ill as in rheumatic fever. The joints are fewer in number, and, as in pyæmia, the course of the individual involvement is much longer. The inflammation, too, affects peri-articular as well as articular structures; not seldom it involves adjacent tendon sheaths also. Gonococci may be isolated from the joint effusions. Although the presence of a urethral or vaginal discharge makes a diagnosis of gonorrhæal arthritis likely it does not prove it; and it must be remembered that the discharge not infrequently ceases temporarily with the onset of the arthritis.

(4) Acute osteo-arthritis is a rare disease, but when it occurs it produces a clinical picture that is probably closer to rheumatic fever than does any other disease-process. The patient is more often a woman than a man, and is generally older (30 to 60) than is the average case of rheumatic fever. The failure of salicylates in full doses to reduce the temperature, and to affect beneficially the course of the joint condition, should always raise doubts as

to the nature of a supposed case of rheumatic fever. This differential point applies equally to diseases 1 to 3.

(5) *Gout*, when present in the acute arthritic form, may be mistaken for rheumatic fever; rarely does the converse happen. The patient is generally a man over 40 years of age; the number of joints involved is rarely more than two; the skin over these is generally dusky red in hue, and shining; there is often definite soft oedema. *The presence of severe pain when the affected joints are at rest is much in favour of gout.* The degree of fever is usually much less in proportion to the degree of joint inflammation than is the case in rheumatic fever. The presence of tophi may be taken as confirmatory of gout in a doubtful case.

(6) *Meningococcal meningitis with arthritis* rarely simulates rheumatic fever, but the writer has seen such a case, in which there were pungent acid sweats and purpura, and the resemblance to a case of severe rheumatic fever was for a time very close indeed.

Prognosis.—Recovery is the rule in this disease; *death during a first attack is very uncommon.* When death occurs there is invariably serious carditis, especially myocarditis, and acute pulmonary complications (pleurisy and "rheumatic pneumonia") are usually present also. In rare cases, death occurs in a state of hyperpyrexia. When the attack supervenes upon old rheumatic carditis, the prognosis is less good, heart failure being more easily induced. But in general it may be said that rheumatic fever is serious, not from its case mortality, but from its crippling effect upon the heart. *Residual conditions* are almost entirely cardiac injuries and chiefly scarred valves; rarely some degree of limitation of movement in joints.

Treatment.—(1) *General.*—With as much promptness as possible, the patient is put to bed, and is kept there until it is certain that the heart is unaffected, or, if affected, until it is certain that the inflammatory process has ceased to be active (see p. 823). The bed should be chosen carefully; narrow enough to admit of easy nursing, and having a soft but firm mattress. The patient lies in blankets with a long flannel garment opening down the front, and having sleeves to the wrists; this garment is changed as frequently as need be, according to the degree of sweating. The position of the patient is one of recumbency, with the affected joints supported in a position of maximum comfort. Movements of the limbs are generally best carried out by the patient's own efforts, and in all except severe cases, and where the heart is affected, movements of the body as a whole may also well be left to the patient. The basis of the *diet* should be milk diluted with water or alkaline mineral waters, and so long as the fever remains a marked feature of the case nothing should be added to this unless it be whey, peptonised milk, or barley water. Abundance of fluids should be allowed, for a great deal of fluid is lost to the body through the profuse sweats. Imperial drink is very useful. As the fever declines, there may be added to the milk, oatmeal, vegetable soups and chocolate. Meat should be reserved for convalescence, and even then should be given very sparingly. Tea and coffee are best omitted altogether. Fruit is disallowed. Aperients are given as necessary.

In the matter of *drugs* there is a consensus of opinion that salicylic preparations deserve the name of specific remedies. They control the arthritis, cause the fever to decline, and cut short the course of the disease-process. They also lessen the tendency to relapses, and often render these abortive

when they threaten. It may be quite true that they do not prevent the occurrence of endocarditis, nor affect this inflammatory process beneficially when once established, but a remedy which cuts short the course of a disease must necessarily, in an indirect measure, act as a deterrent in respect of its complications. Thus, by prompt exhibition of salicylates an attack of rheumatic fever may be almost resolved by the eighth day, at about which period in the disease acute endocarditis is specially liable to develop. Certain it is that pericarditis, and in particular pericarditis with liquid effusion, is much less common nowadays than it was in the pre-salicylic days; so also is hyperpyrexia; and it is unlikely, in view of the more general features of rheumatic fever and its incidence, that the disease-process has itself undergone any change during the past 25 years which is likely to account for these facts. The preparation of the drug which has become most popular, and deservedly so, is salicylate of soda. *It should be given in sufficient quantities, and the doses should be distributed as evenly throughout the 24 hours as is compatible with securing good sleep for the patient.* At the onset of treatment of an acute case in an adult, 10 grains may be given every 2 hours during the day, and every 4 hours during the night (90 grains in the 24 hours). As the fever and pain diminish, these quantities may be given somewhat less frequently, a note being kept on the temperature chart of the total amount given in the 24 hours. In a child of 12 years or so, half these quantities may be given. If no amelioration follows these doses in 48 hours they should be increased by 50 per cent. (135 grains in 24 hours). If an exacerbation occurs, or a relapse threatens, after the dosage has been reduced, it should be at once adjusted to its original level. The drug is not unpleasant to take, unless an effort be made to render it palatable by the addition of a flavouring agent. Quite apart from the inestimable value of giving adequate doses so as to gain time, there is an additional value in this procedure from the point of view of diagnosis, for a patient suffering from acute arthritis with fever, who is not considerably better after 48 hours' treatment by full doses of salicylates, almost certainly is not suffering from rheumatic fever. The diagnosis in these circumstances should be at once revised. It will be found that the great majority of patients tolerate the above specified doses of salicylates without ill-effects. In the few instances in which it produces vomiting, or intense depression, or delirium, or hæmaturia—symptoms thought from time to time to be toxic effects of the drug—either aspirin in similar doses, or salicin in somewhat larger doses, may be substituted. But care must be taken in deciding that such symptoms are really due to the salicylate and are not manifestations of the rheumatic poison. Modern synthetic preparations of salicylate of soda are fairly free from the contaminations which were formerly rather common. But as an additional safeguard, and in case of doubt, the physician may specify the natural product, which is certain to be free from carbolic derivatives, though it is much more expensive. Salicylate of soda is so efficacious that the young practitioner is warned against experimenting with the other salicyl preparations. Salicin is said to be less depressing, and is sometimes recommended as the best drug for children, but the writer's experience of this preparation is very disappointing. Of oil of wintergreen given internally he has had no experience. The "alkaline" treatment has been almost superseded by the salicylates, but to-day it survives in the form of a recommendation to "cover" the salicylates by

large doses of sodium or potassium bicarbonate. Lees, in particular, claims that by this use of alkali the depressing effects of salicylates are to a large extent avoided. In the early stage of the disease it may be necessary to adopt more rapid palliative measures for the severe pain, especially if this prevents sleep. Nothing is better than opium, either as pulv. ipecac. co., grs. x, or pil. saponis co., grs. x. It is better to avoid antipyrine and phenacetin. The treatment of heart complications is discussed elsewhere (Sect. XII.). Against the occurrence of these complications, apart from the value of early and liberal use of salicylates, we seem to be powerless. But some authors attach importance to small blisters applied to the præcordium early in the disease.

Hyperpyrexia is met by prompt application of the cold pack, with volatile stimulants; the pack may need frequent renewal, and in extreme cases the water used for it must be iced. The most constant vigilance is necessary in such cases, which, as already stated, are happily rare nowadays.

In the treatment of prolonged cases of the disease the writer believes iodine (preferably not in the form of the potassium salt) to be useful, and especially so in cases complicated by serous inflammations, whether cardiac or other. Such experimental treatment of these prolonged cases by sera and vaccines as the writer has observed has not led him to employ either of them in any routine fashion. "Channels of entry" should, in protracted cases, be adequately dealt with as in (4).

(2) *Local*.—The position of optimum comfort of the affected joints has been already referred to. The use of splints for fixing the joints often gives relief. In the milder cases it suffices to wrap the joints in cotton-wool and bandage them lightly. In the more severe cases a lotion of tinct. opii, 1 oz.; glycerin, 2 oz.; water, 12 oz.; sod. carb. to saturation, used hot, gives as much relief as anything. An alternative is one of the preparations of winter-green, used freely, but without rubbing. Aspiration of the effusion is scarcely ever needed; its indication, indeed, should raise doubts as to the diagnosis.

(3) *During convalescence*.—Convalescence is generally slow, and should not be hurried. If the heart has suffered by direct inflammation, the recumbent position must be prolonged until it is certain that quiescence is established in that respect; this usually means from 4 to 6 weeks after the subsidence of the fever. The disastrous effects of attempting to hasten convalescence in such cases are to be seen amongst patients who have been treated in institutions which advertise a false efficiency by reporting a "shorter average stay in hospital" than is the case in sister institutions. The transition from strict recumbency to a sitting posture should occupy a whole week, by the gradual addition of pillows, and the further return to ordinary active life should be graduated with care.

Tonic preparations, such as quinine and hypophosphites, are useful, but the tradition that iron is not well tolerated until late in convalescence—though the state of anæmia seems to indicate it—is confirmed by experience. Diet during convalescence has already been referred to. Massage and passive movements of the affected joints may be begun so soon as the inflammation has completely subsided.

(4) *Preventive treatment*.—Failing exact knowledge of the essential causative agent in rheumatic fever, no effective mode of prevention can at present

be devised. But if there be a doubtful "channel of entry" present in any case, this should be dealt with in some radical fashion, in any patient who has had an attack, or is a member of a susceptible family. "Septic" tonsils should be enucleated, and an appendix which has at any time shown signs of inflammation should be removed. The writer has on one occasion, at least, witnessed the complete subsidence of a prolonged and recrudescing attack of undoubted rheumatic fever after the removal of dead teeth, the roots of which were infected.

ERYTHEMA NODOSUM

Although this disease is a fairly definite and easily recognisable clinical entity, it is still uncertain where it should be placed, when considered in relation to nosology or to pathology. According to some authorities it is related to the purpuras, according to others it is most appropriately grouped under Erythema multiforme, whilst some still consider it, as did S. Mackenzie, whose collection of cases remains the most extensive in the literature, a manifestation of true rheumatism. Since it is less often than not associated with the more definite criteria of acute rheumatism (arthritis, endo- and pericarditis), since it rarely recurs in the same patient, and since treatment by salicylates in full doses does not cut short its course, it is very doubtful if it should be regarded as a true rheumatic affection.

Ætiology. The ætiology of the disease is obscure. It is possible that the condition is not due to one specific factor, but to one of several factors, as is purpura.

It occurs more often in females than in males (according to Mackenzie in the proportion of five to one), and the majority of cases are found between the ages of 10 and 30 years. There is no seasonal incidence. In the experience of the writer it is, like the purpuras generally, much more common in hospital than in private practice; this and some other observations suggest that bad feeding or insanitary conditions may contribute to the incidence of the affection. Typical cases have been described in tuberculous patients, and Osler states that guinea-pigs have been successfully inoculated with tubercle bacilli from the lesions.

Symptoms.—The symptoms consist of—(i.) the local lesions, and (ii.) certain constitutional changes.

(i.) The local lesions are bilateral and occur chiefly upon the lower limbs; indeed, in the great majority of the cases they are confined to these. When they appear on the arms they are most often found only in this situation, the patient is more often than not an adult, and the general symptoms are less like rheumatic manifestations than is the case in the more common variety of the disease. The lesions are round or oval swellings, usually confined to the extensor aspect of the limbs, affecting the shin regions chiefly, and varying in size from a large pea to half an orange. There may be two or three only on each leg, or, in severe cases, the greater part of the extensor surface may be covered by them. They involve the subcutaneous tissue as well as the skin. They are very tender to touch. On their first appearance they are deep red in colour, later they become purple in hue, and still later they often show a definite ecchymotic appearance—giving rise to the

name *Dermatitis contusiformis*. In bad cases there is a good deal of associated œdema of the surrounding tissues.

(ii.) The general symptoms include a mild grade of fever (not constantly present), joint pains, malaise and sore throat. But many cases occur in which the local skin condition, with pain and tenderness, covers the whole of the symptomatology. Constipation is common, and is sometimes severe; in a case of the writer's, in a young man, there had been no action of the bowels for 10 days, and the patient had suffered from constipation all his life.

The course of the disease is from 2 to 3 weeks, but some mild cases get well, if treated, within a week.

Diagnosis.—The diagnosis is not difficult. Radcliffe-Crocker says that the lesions may be mistaken for syphilitic nodes: the distinction is made by the presence of other signs of syphilis, and by the fact that the pains in the latter disease precede the appearance of the node through the skin.

Treatment.—Rest in bed, with the legs elevated, and general hygienic conditions, suffice to bring about spontaneous recovery in all cases. No drug has credit for cutting short the course of the disease. The writer has found progress to be quite as rapid when the patient is treated by small doses of hydrarg. c. cretâ with saline aperients, as when she is given full doses of salicylate of soda. As a local application, lead lotion is perhaps the most soothing.

THOMAS HORDER.

TRENCH FEVER

Definition.—A blood infection communicable from man to man by means of the louse (*Pediculus humanus*). Characterised by recurrent pyrexia, headache, giddiness, pain in the back, pain in the limbs, conjunctival congestion, sweating, moderate leucocytosis at the height of the fever, and slight enlargement of the spleen.

The infection is often very persistent, and acute febrile relapses may occur after months of quiescence. The disease was first recognised as a specific entity during the Great War, when it appeared on all the European fighting fronts—800,000 being the approximate number of cases occurring in France among the Allies during 4 years, and sporadic infections have been reported among those coming into contact with returned troops in England and elsewhere.

Ætiology.—Trench fever being transmitted by lice alone, its occurrence depends on the presence of these insects and of human carriers of the infection. As with other insect-borne diseases, considerable numbers of the vector are required before an epidemic is produced, and close contact between human beings is necessary to facilitate the transference of the lice. Both the body louse and the head louse are capable of conveying infection. The disease is conveyed by the excreta or crushed bodies of infected lice; the virus may enter through the broken skin or unbroken conjunctiva; rubbing and scratching promote infection, but the bites of the lice may cause a sufficient lesion to enable infective material to enter the body.

The causal organism.—No observer, as yet, has succeeded with certainty in demonstrating the organism of trench fever in stained or fresh blood

preparations, though it is known that the blood of patients is infective both during fever and in the afebrile intervals and for many months if symptoms persist. Further, the blood plasma has been shown to contain the infective agent, which in this condition is capable of passing through a Pasteur-Chamberland filter (L) with 740 mm. of mercury vacuum. Arkwright, working with excreta from lice fed on trench-fever patients, has shown that the infectivity of the excreta for man varies very closely with the presence or absence of *rickettsia* bodies.

Pathology.—Very little can be said under this heading. Though German writers refer to fatal cases of trench fever, no reliable accounts of post-mortem examinations are available, and we have no knowledge of any death caused by this disease.

Symptoms and Course.—The incubation period, as evidenced by experimental infections with louse excreta, is most frequently 7 to 9 days, but the period has been prolonged to 16 days when minute doses of louse excreta have been inoculated.

The onset of the disease is sudden in the majority of cases, though about 25 per cent. of all patients complain of prodromal symptoms, such as headache, generalised pains, weakness, diarrhoea, constipation, restlessness, or insomnia, for a day or two before the temperature rises. In some instances the onset is quite dramatic in its suddenness, the patient collapsing while out walking, or even falling from his horse. Early giddiness is a common complaint, and may be so marked that the sufferer has difficulty in returning to his home. Chilly sensations frequently usher in the attack, but true rigors are extremely rare. Nausea, vomiting, and diarrhoea occur in a small percentage of cases, and a gastro-intestinal type of trench fever has been recognised by Plesch and others.

Many cases are extremely mild. Slight fever may be the only symptom, and though complaining of pains, some patients may be entirely afebrile throughout their illness.

The temperature rises rapidly as a rule, and may reach 103° to 104° F. (39.4 to 40° C.) within a few hours of the onset of symptoms. A study of the chart reproduced (Fig. 6) will reveal the main features of the course of the fever; the curve may be extremely erratic. The pulse is usually accelerated, its curve corresponding to that of the temperature, its rate varying from 90 to 120 in men of military age. In old age the rate may be slow. The systolic blood pressure is slightly raised and its curve corresponds with that of the pulse. The respiration rate is normal, and pulmonary complications are extremely rare.

In the fully developed attack, the patient's three chief complaints are headache, pain in the small of the back, and pain in the limbs. The headache is most commonly felt across the forehead and behind the eyes; usually one of the earliest symptoms, it is often one of the most severe, persistent, and commonly recurrent. When occipital, it is often accompanied by stiffness in the back of the neck. The character of the pain in the limbs is twofold: (a) Dull aching or gnawing, more or less continuous, always worse at night; and (b) acute pain—shooting or stabbing—which may last many hours, especially at night. This latter pain is nearly always felt in the bone and, most frequently, in the tibia. There is no part of the body which invariably escapes from pain. After a few days, however, the "pain all over" sub-

sides and localised pain becomes prominent. The loins and lower limbs are most often affected. Pain is usually, but not invariably, symmetrical; its situation may vary from day to day. The pain complained of in the left hypochondrium points, in most instances, to involvement of the spleen. In early cases the splenic region is frequently so tender that examination by palpation is impossible, on account of stiffness of the muscles over the organ. When the spleen is felt, its edge is well defined and firm. Its actual size, however, varies from day to day in the early stages, and does not remain constant until late in the disease. It is often observed to increase suddenly with the relapses and decrease during the afebrile periods (Day). An appreci-

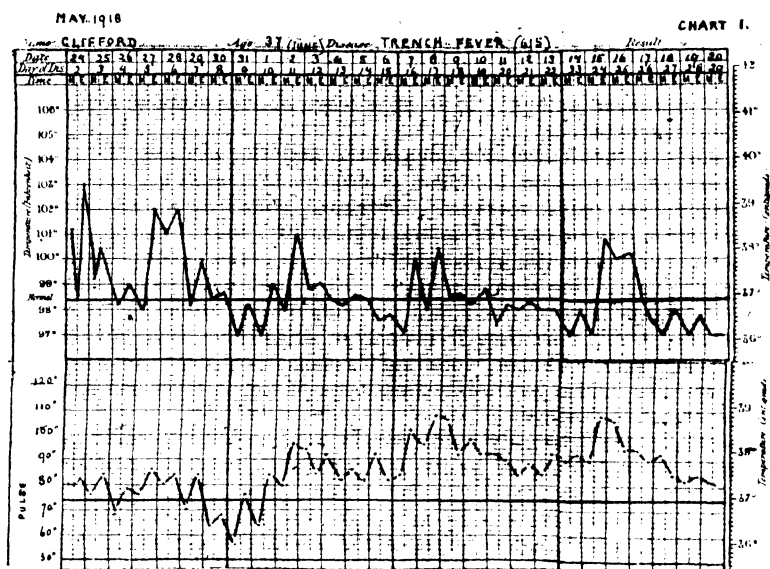

FIG. 6.—Trench fever. Typical temperature and pulse curves.

able percentage of all our cases have had palpable spleens during some period of the disease, though such enlargement has never been more than two finger-breadths below the costal margin. Definite enlargement is most often the result of a prolonged infection, and such enlargements may persist for many months after the patient has resumed his normal life. Areas of tenderness are frequently associated with the pains, and may involve the spleen, tendons, bones, or joint cartilages. The nerve trunks themselves do not appear to be involved. Such tenderness may occur independently of pain, or *vice versa*, and either or both may persist for long periods after the fever has subsided. The extent of the areas of tenderness usually increases with exacerbations of the disease, which exacerbations may be entirely afebrile. As with the pain, the areas of tenderness are usually bilaterally symmetrical, the shin from knee to ankle along the outer border of the tibia being most frequently involved.

The general appearance of the patient during the acute fever suggests a condition of extreme discomfort. He is restless, moving constantly to relieve the pain, and always failing to find comfort. A fairly constant feature of the initial attack is a mild degree of conjunctival congestion; it is usually transient, but frequently recurs with subsequent rises of temperature; this "pink-eye" is not accompanied by increase of secretion. At first the tongue is slightly coated with cream-coloured fur, though there is nothing characteristic about its appearance: it soon clears, and remains remarkably clean. A peculiar and very constant feature is the rapid alternations of shivering and sweating, such alternations occurring several times in the course of a single day or night. Profuse sweating, however, is rare. Rose spots upon the chest and abdomen are frequently seen during the first few days of fever. "They appear in crops, are fairly uniform in size (4 to 8 mm. in diameter), with fairly well-defined edges, varying in hue from bright pink at first to a dull red colour later. They disappear on pressure and are not raised, although vesiculation has been observed in a very few cases. They last from 6 to 48 hours and disappear suddenly, leaving no stain; at times they make their initial appearance during the relapses, which may be afebrile" (H. Fairley Marris).

The mental condition remains normal throughout the disease in the great majority of cases, though rarely there may be some delirium in the most acute attacks. The tendon reflexes are exaggerated, and a pseudo ankle clonus is often found. During fever, lateral nystagmus on extreme deviation of the eyes is common. Frequency of micturition is complained of by about 13 per cent. of all cases, and is not associated with pain, but results in the passage of an increased amount of urine. A trace of albumin is often present. The polyuria occurs as the temperature falls.

The blood picture indicates abnormal activity of the bone marrow, and a moderate and rapidly varying leucocytosis precedes and accompanies the fever waves. The count rarely exceeds 20,000 leucocytes per c.mm. The increase of white cells is due to outpouring of immature polymorphonuclears up to 80 per cent. or more of the total. In the afebrile intervals the mononuclear elements are relatively increased. This last is probably a condition common to many soldiers in the field. In chronic cases the total of red cells is increased, the colour index as a rule being about 0.8.

Progress of the case.—When a definite afebrile interval occurs between the initial fever and the first relapse, all symptoms usually subside as the fever abates, to return as the temperature rises. In prolonged cases, the patient's general condition obviously deteriorates and he presents an appearance of exhaustion. As relapse succeeds relapse the intervals bring less and less relief, though in some cases the later fever waves are accompanied by singularly few symptoms. The body weight steadily declines. Usually, after a period varying from a few days to about a fortnight from the onset of the disease, the acuteness of the patient's pain subsides, he sleeps well, and his appetite returns. There is even then generally some return of pain each night in some part of the limbs—most commonly the shins, calves, or ankles. If he be allowed to get up he finds walking increases the pain. During the next week or two, whether pyrexia recur or not, there are recurrences of symptoms—especially leg pain, each exacerbation being a short replica of the original attack, or of some portion of it. In some cases such recurrences are few and

slight, and the patient soon feels fit and complains of nothing but slight pain or still slighter tenderness in a limited area of the legs, from the knees downwards. In others the recurrence, even if quite late in the disease, as after months of quiescence, may be more severe than the original attack.

The chronic disease.—It has become evident, in a large proportion of the cases of trench fever invalided home, that there is a tendency to advance through a subacute towards a chronic condition, with symptoms of disordered action of the heart, and also in some of neurasthenia. Breathlessness on exertion, palpitation, præcordial pain, and giddiness are features of the subacute and chronic conditions. The temperature in these chronic cases varies considerably; definite fever waves lasting from a few hours to several days occur at irregular intervals, which frequently are to be measured in months.

Diagnosis.—The acute disease may be mistaken for the enteric fevers, malaria, cerebro-spinal fever, influenza, dengue, rheumatic fever, European relapsing fever, typhus, rat-bite fever, or mild infective jaundice with absence of jaundice and albuminuria. Trench fever in the chronic form is particularly liable to be mistaken for some form of cardiac disease, neurasthenia, myalgia or chronic rheumatism; and, in addition, must be differentiated from other chronic infections, such as malaria, dysentery, and tuberculosis.

Prognosis.—Trench fever is practically a non-fatal disease, but may result in prolonged ill-health in from 10 to 20 per cent. of all those affected. A certain degree of immunity follows an attack of trench fever, more particularly when the attack has resulted in a complete clinical recovery; and it has been shown experimentally that such immunity may persist for six months.

Treatment.—The prospects of prophylaxis against lice-borne disease are more hopeful than in the case of any other insect-borne malady. In all their stages, lice have no normal life apart from their host, and may thus be made the subject of complete control. It is a simple matter to free the individual from lice, and as regards the community this depends on successful organisation. The sick should be immediately and completely freed from vermin; but their isolation alone is not likely to control the spread of an epidemic, as mild cases are apt to escape recognition, and chronic cases remain infective for too long a period to permit of segregation till all danger is passed. The curative treatment is mainly symptomatic, the chief indication being to get the patient to bed as early as possible, and to keep him there for 8 days after the fever has subsided. In this way the incidence of chronic symptoms has been reduced. Chronic cases are best treated by healthy open air exercise, with tonics and small doses of thyroid extract. Even when complaining of shin pain it is a mistake to allow such cases to live a sedentary indoor life.

W. BYAM.

HYDROPHOBIA

Synonym.—Rabies.

Definition.—Hydrophobia is an acute infective disease of dogs, wolves and some other animals, communicable to man by the bites of such infected animals.

Ætiology.—The disease can also be communicated by the licking of an

abraded surface, and is communicable from man to man by bites. In Western Europe man is almost always infected by rabid dogs, but in Eastern Europe wolves provide the commoner origin. Infections from rabid dogs were said to occur in 16 per cent. of bitten individuals, whereas 80 per cent. of cases bitten by rabid wolves are said to become infected. Inasmuch as the lesions caused by wolves are more extensive this increased infectivity may depend on the amount of virus introduced.

Pasteur demonstrated that rabies was essentially an infection of the central nervous system by injecting experimental animals subdurally with emulsions of any part of the nervous system of infected animals, and reproducing the disease. Further experiments showed that the virus, gaining admission by the infected wound, reached the central nervous system by spreading up the peripheral nerves. Thus di Vestea and Zagari showed that the lumbar cord of an animal inoculated in the sciatic nerve is infectious several days before the virus can be shown in the brain. An explanation is therefore forthcoming of the fact that in cases bitten about the head the incubation period is short.

The virus of rabies.—It was shown by Remlinger and Riflat-Bey that the virus of rabies would pass through a coarse Berkefeld or Chamberland filter. Animals killed by such filtrates provided virus that would communicate the disease to further animals. Finer filters produced a filtrate capable of killing animals, though the disease could not be again propagated. Hence symptoms and death may be caused by a toxin containing no living virus. The virus is destroyed by a temperature of 50° C. for one hour, and is attenuated by drying.

In 1903 Negri described bodies, known as Negri bodies, which are now universally considered to be specific to the disease. They are present in all portions of the brain in 98 per cent. of cases of rabies in dogs, as well as in other animals and man. Much controversy has occurred as to whether these bodies are parasites, or simply degenerated cell products caused by the ultra-microscopic parasite of the disease. The balance of opinion tends to the theory that they are parasitic. The cultivation of the parasites entirely failed till Noguchi employed similar methods to those by which he cultivated *Spirochaeta pallida*. He preserved the virulence of the virus through 21 generations, covering a period of 100 days.

Symptoms.—The *incubation period* varies from 15 days to 7 or 8 months, but it is usually about 40 days. Three stages are described in the symptoms.

1. *The invasion stage* includes certain local symptoms in the region bitten, such as irritation or pain. But these local symptoms may be absent. There is very moderate pyrexia, the pulse is raised in frequency, headache is common, and some restlessness and insomnia.

2. *The stage of excitement* follows after a period of 2 or 3 days, and itself lasts about the same time. It is characterised by intense restlessness, mental excitement, and great and generalised hyperæsthesia. Any stimulus to any of the special senses, or to the mind, leads to spasm affecting the muscles of the mouth, pharynx and larynx. Laryngeal and pharyngeal spasms are immediately induced by any effort at drinking. This stage is usually marked by a higher temperature. Mania may occur.

3. *The paralytic stage* ends the scene, the patient lying exhausted and unconscious; death occurs from heart failure after 1 or 2 days in this condition.

Diagnosis.—This presents no special difficulty, but some cases of neuro-

mimesis (lyssophobia) or hysteroid counterfeiting of the disease are said to resemble it rather closely. These patients are not ill, however, and they are very emotional. Tetanus is probably the infective disease which bears the nearest resemblance to rabies.

Prognosis.—When once the disease is established no hope of recovery exists. Reported recoveries are probably cases of pseudo-hydrophobia (lyssophobia).

Treatment.—This is entirely preventive.

1. Local measures.—Cauterisation of a rabies wound within 5 minutes of its occurrence prevents development of the disease; within half an hour of infliction cauterisation prevents a certain proportion of cases from developing. Subsequent cauterisation tends to prolong the incubation period, and the prolongation thus obtained is of great importance when specific prophylaxis is undertaken.

2. Specific therapy.—Pasteur published his researches in 1885. He showed that rabies virus obtained from rabid dogs—"street virus"—had a nearly constant virulence, in that it killed rabbits in 15 to 20 days when inoculated subdurally. By passing this street virus through a series of rabbits, the virulence became gradually raised till it remained constant at a titre, when it killed rabbits in about 7 days. He called this *virus fixé*. Similar passages of street virus through monkeys attenuated the virulence. He thus had various strengths of virus at his command, and he found that, commencing with a weak, and gradually working up to a strong, virus, he could by subcutaneous injections so immunise a dog that subdural inoculation with a strong virus was not fatal.

Subsequently he devised a method for attenuating the virulence of infected rabbits' spinal cords by drying in air over caustic potash. The next step was to inoculate a man bitten by a rabid dog with emulsions of these dried cords. Commencing with a cord that had been dried for 14 days he gave doses of emulsion of cords of increasing virulence till by the ninth day he completed the series of 12 inoculations with a dose of a cord that had been dried for 1 day. No sign of hydrophobia supervened, and with only slight modifications this still constitutes the famous Pasteur prophylactic treatment.

Högyes states that 50,000 people have been treated within 10 years with an average mortality of but 1 per cent.

THOMAS HORDER.
JOHN MATTHEWS.

EPIDEMIC JAUNDICE

Jaundice may occur in the form of outbreaks which may be due to—(1) some specific disease of which jaundice is a symptom, such as influenza, yellow fever, relapsing fever, malaria, etc.; or (2) some chemical poison capable of producing toxic jaundice, which may act on a large scale on a number of persons exposed to it and an outbreak of jaundice result. Examples of this occurred during the Great War, from tetrachlorethane poisoning in connection with the manufacture of aeroplanes, and from poisoning by trinitrotoluene and other similar substances used in the manufacture of munitions (*vide* Lettsomian Lectures, 1919; Willcox).

The term "Epidemic Jaundice" is not applied to the above types, which

are named after the disease or poison causing the jaundice. The term is restricted to—(1) Epidemic catarrhal jaundice; (2) Infective hæmorrhagic jaundice occurring in—(a) *Spirochætosis ictero-hæmorrhagica*, (b) Weil's disease, and (c) Mediterranean yellow fever.

1. EPIDEMIC CATARRHAL JAUNDICE

This is a type of jaundice often occurring in large outbreaks where the symptoms resemble those of ordinary catarrhal jaundice, and, in addition, there are some symptoms of a mild general infection.

Ætiology.—Occurrence.—Serious outbreaks of this disease have occurred in recent wars. Thus, in the American War 22,509 cases occurred, with 161 deaths; in the South African War 5648 cases occurred, with a few deaths; and in the Great War the disease was of very common occurrence. In the Mesopotamian campaign during 1917, 1538 cases occurred in British troops, the mortality being 0·6 per cent.; and there were 2633 cases in Indian troops, the mortality being 0·3 per cent. Localised epidemics have occurred in civil life in this country; thus in 1918 a small outbreak in Cambridgeshire was reported by Dr. G. S. Gray, and Dr. S. Hartill investigated a similar outbreak in 1918 in Hertfordshire.

Infection.—This is probably gastro-intestinal in origin. In the Dardanelles and Mesopotamian campaigns, the incidence curve followed that of dysentery and diarrhoeal diseases, the maxima for jaundice occurring about 3 weeks after those for diarrhoeal diseases, thus indicating a similar channel of infection. The epidemic character of the disease is beyond doubt, since there were numerous instances of large numbers of cases occurring amongst a single unit. The epidemic character appeared to be due to a common cause, rather than to a spread from person to person, for infection from one case to another in hospital was uncommon. Defective sanitary conditions whereby food is contaminated by dust, flies, etc., and where the drinking water is polluted, strongly predispose.

Age and sex do not appear to have any influence on the occurrence. The disease occurs in all climates, but the maximum incidence is in the cold months. There is sometimes a history of diarrhoea for several days before the onset of jaundice, and the disease has often occurred during the course of an attack of dysentery.

Pathology.—No specific organism has been isolated from the blood in this disease during life, and this is not surprising, since the signs of general infection have usually disappeared by the time that jaundice has developed. Organisms of the *B. coli* group have been obtained during life, and post mortem from the liver on several occasions. Bacteriological examination of the duodenal contents after withdrawal by means of Einhorn's evacuator has failed to yield any definite results (Martin and Hurst). In two fatal cases in the Dardanelles, a marked duodenitis was present, and there was redness and swelling of the mucous membrane of the common bile-duct, the catarrhal condition spreading up the cystic and hepatic ducts. Usually, however, in cases of epidemic catarrhal jaundice, when death occurs, it is at a late period of the disease, from acute atrophy of the liver, so that the signs of the original duodenal infection have largely disappeared. Paratyphoid infections may be associated with catarrhal jaundice, but the clinical course of

Handwritten notes:
The epidemic curve is similar to that of dysentery and diarrhoea.
The incubation period is about 3 weeks.

these cases is that of paratyphoid and not of epidemic catarrhal jaundice. It seems probable that the disease is caused by an intestinal infection setting up a duodenitis and ascending catarrh of the bile-ducts, with resulting obstructive jaundice, and in the uncommon fatal cases the infection causes such degenerative changes in the liver cells as to lead to the symptoms of acute yellow atrophy. The organisms causing the disease may be similar in type to those found in health in the intestinal tract, such as the *B. coli communis* group.

Symptoms.—In some cases, there is a history of diarrhoea or dysentery during the previous few weeks. Usually there is a prodromal period, lasting a few days, in which anorexia, nausea and perhaps occasional vomiting occur. Diarrhoea frequently occurs during this period, but sometimes constipation is present. Pyrexia of a mild type now sets in, with some chilliness and occasionally shivering. The tongue is furred, and headache and general pains, with perhaps vomiting, may occur. Some discomfort in the hepatic and epigastric region is present. The pyrexia usually lasts from 2 to 4 days, but may be longer or shorter. About the third or fourth day of fever, jaundice occurs, at first slight, but gradually deepening, and becoming of the obstructive type, with pale stools and bile-stained urine. The jaundice attains its maximum in about 10 days and then gradually subsides. Definite uniform enlargement, with some tenderness, of the liver occurs as the jaundice develops, and in about 10 per cent. of cases enlargement of the gall-bladder can be detected. Enlargement of the spleen accompanies that of the liver, and it can usually be felt extending half an inch or more below the left subcostal border in inspiration. The enlargement of the liver and spleen diminishes as the jaundice subsides. The pulse is quickened to 80 or 90 per minute during the pyrexial period, and there is definite increase in the area of cardiac dullness to the right of the sternum. The dullness on percussion in the fourth intercostal space may extend to 1 or 2 inches to the right of the sternum, and this is a very characteristic sign. Anæmia, herpes, conjunctival congestion and hæmorrhagic symptoms do not occur in this disease. The urine shows the usual characters of obstructive jaundice, and albumin and casts are only present in those rare and fatal cases which develop icterus gravis. During the course of the attack, definite impairment of hepatic efficiency can usually be demonstrated by the lævulose tolerance test (Stokes). This proves that an actual involvement of the liver (hepatitis) occurs.

Prognosis.—Usually cases of epidemic catarrhal jaundice give rise to no anxiety and the jaundice gradually clears up in about 3 weeks, so that signs of pruritus, etc., do not occur. The convalescence is somewhat slow, especially in cases with marked hepatic and splenic enlargement, and 2 or 3 months are required before the patient is fully restored to health. In a few cases (about 0·5 per cent.) the disease runs a more severe and often fatal course. About 10 days after the onset of the jaundice in such cases, mental irritability, vomiting and stupor occur; subsultus tendinum, Cheyne-Stokes breathing, coma and a rise of temperature supervene, and death commonly occurs within about 3 days of the onset of these grave symptoms. Hæmorrhages such as hæmatemesis, epistaxis or hæmaturia may occur during this stage, and the urine contains albumin and casts, and may be suppressed. The clinical symptoms are those of icterus gravis, and the signs

found post mortem are those of acute yellow atrophy of the liver. Before death a marked diminution in the liver dullness can be made out. Fortunately, the occurrence of acute yellow atrophy of the liver is uncommon, but its possibility always renders cases of epidemic catarrhal jaundice serious.

Treatment.—Rest in bed, light diet of lacto-vegetarian type, in which proteins and fats are restricted, an alkaline mixture of citrate of potash and bicarbonate of soda, and saline aperients are all that are needed. Small repeated doses of calomel should not be given, since mercurial stomatitis may be caused. In cases where symptoms of icterus gravis threaten, bicarbonate of soda, half a drachm every 2 hours, should be given by the mouth, and injections of normal saline containing bicarbonate of soda, 2 drachms to the pint, should be administered per rectum as frequently as they can be retained. In severe cases, normal saline containing 1 drachm of bicarbonate of soda to the pint should be given intravenously. In some cases by this treatment the dangerous symptoms may be warded off.

2. INFECTIVE HÆMORRHAGIC JAUNDICE

(a) *Spirochaetosis ictero-hæmorrhagica* (see p. 183, under *Spirochætal Infections*).

(b) *Weil's disease*.—This is a form of infective hæmorrhagic jaundice similar in many respects to the spirochætal form just mentioned. It was first described by Weil in 1886, and German physicians claim that it is not identical with spirochætal jaundice. The disease does not appear to occur in this country, and it must be classified amongst the "Hæmorrhagic Infective Jaundice group," further bacteriological investigations being necessary before a specific organism can be assigned to it.

Pathology.—The *B. proteus fluorescens* has been found in the urine and organs in fatal cases, but not during life in the blood of those affected with the disease. It has been stated that the disease is conveyed by the drinking of polluted water or the eating of contaminated cheese or meat.

Symptoms.—The disease is an acute one, with sudden febrile onset and marked gastro-intestinal symptoms. Jaundice occurs from the second to the fourth day. The liver and spleen are enlarged, and albuminuria and nephritis often occur. Hæmorrhagic symptoms, such as purpuric rashes, epistaxis, hæmoptysis and bleeding from the stomach and bowels, occur in severe cases.

(c) *Mediterranean yellow fever*.—This disease was described by Kartulis as occurring in Alexandria, Smyrna and Nauplia, and must be regarded as a very toxic form of hæmorrhagic jaundice of unknown causation.

Pathology.—No specific organism has been found in this disease, but it has been associated with defective drainage and inadequate sewage disposal.

Diagnosis.—The disease differs from yellow fever in the late development of jaundice.

Prognosis.—The mortality was high, being from 30 to 75 per cent., and death usually occurred from the tenth to the sixteenth day.

Symptoms.—It is an acute febrile disease, with very severe toxæmia, in which jaundice occurs about the fourth or fifth day, with marked hepatic

enlargement. Purpuric rashes, hæmorrhages from the nose, bowel and kidneys are common, and nephritis with suppression of urine frequently occurs.

W. H. WILLCOX.

YELLOW FEVER

Definition.—A specific febrile complaint associated with characteristic symptoms, endemic in parts of tropical America and also on the West Coast of Africa, the parasitic cause of which is unknown, the virus being filterable and transferred from man to man by the agency of the common domestic mosquito *Aedes ægypti* (formerly *Stegomyia fasciata*).

Ætiology.—The endemic haunts of yellow fever have been considerably curtailed lately by the general destruction of its intermediary host the mosquito, areas where it used to exist being now completely free. A circle with its centre in the Isthmus of Panama and embracing the northern parts of South America, the West Indian Islands, and the southern parts of North America nearly includes the area of its late prevalence. In addition, however, cases of yellow fever keep cropping up in different parts of West Africa, and the disease must now be looked upon as endemic there. Recently Stokes, Noguchi, and Young, when investigating yellow fever in West Africa, acquired the disease themselves and died of it. In other parts of the world it is unknown.

People born in, and living in, endemic areas of the disease seem to acquire an immunity which is not altogether easy to explain. It has been generally supposed they have had mild infections in their youth and so have become immune, one attack generally conferring this protection. It is certainly the newcomer to an infected place who takes the disease, the so-called *non-immune*; but it is difficult to explain how in some of the West Indian islands that have been free for years, sufficient for a new young generation to grow up, when an epidemic does occur these people seem to escape the complaint. To explain this, Boyce supposed the disease was always present in slight unrecognised forms, but, if so, then certain of the constant stream of non-immunes always arriving would assuredly acquire the complaint, and in them it would be severe, with definite recognisable symptoms. This was what actually happened in the old days in Havana when that town was an endemic focus. Negroes have also been said to enjoy a special immunity, but this is doubtful, as some of the Barbadian epidemics have shown. There is something then still lacking in our epidemiological knowledge of the disease. The organism is an ultramicroscopical one, so small as to be invisible under the highest powers of the microscope, and filterable through the closest filters. It therefore comes under the filterable virus group. Noguchi found a spirochæte *Leptospira icteroides*, and believed it to be the causative agent of the disease. Recent work, however, has shown that the *Leptospira icteroides* is only one of the *Leptospira icterohæmorrhagiae* group, and not the true cause of yellow fever.

The virus is found in the blood of a yellow fever case on the second and third days of the disease, and the *Aedes ægypti* (*Stegomyia calopus* vel *fasciata*) which then sucks the blood takes in the germ. The insect, however, does not itself become infectious until 13 days have passed, this indicating that some

developmental changes have had to take place in the organism. (Compare the development of the malaria parasite in the mosquito, pp. 220, 221.) Once a mosquito becomes infectious it probably remains so for the rest of its life, and as this may be as long as 60 days (Guiteras) it is therefore able to do infinite harm. Some have believed the infection might even spread to the ova and so infect the next generation of mosquitoes, but fortunately this has not been confirmed. Thirty to forty per cent. of non-immunes after being bitten by an infected mosquito acquire the disease, the incubation period usually being 3 days. The ætiology of the disease, then, apart from the actual discovery of the parasite, is complete, the virus existing in the blood and having to pass through the mosquito or intermediate host before it can be transmitted to a fresh individual.

Pathology.—There is little doubt that the pathological changes produced by the causative germ are due to toxins, the changes found at autopsy all pointing in this direction. The skin after death is markedly yellow, and sometimes a post-mortem rise of temperature occurs. The liver is very characteristic, of a bright yellow ranging to a light brown colour. It is in an advanced state of fatty degeneration, with necrosis of the cells and hæmorrhages. The spleen is acutely congested, but about normal in size. The kidneys also show acute congestion and fatty degeneration of the cells of the tubules, a true parenchymatous nephritis often being present. The heart muscle is pale and fatty. The mucosa of the stomach is much swollen, and the organ is generally full of the black grumous material, which, when vomited during life, gives what is called the black vomit. In fatal cases it will be found in the stomach even though not voided during life. Hæmorrhages, chiefly of the nature of ecchymoses, may be found on the pleura, meninges and other places. The brain and lungs show congestion.

Symptoms.—Clinically, the disease may be divided into four, more or less well-defined, types, as follows: (1) Larval; (2) Mild; (3) Severe; (4) Malignant.

1. *Larval forms.*—In epidemics of yellow fever, aberrant or irregular types are often seen—some so slight as to be unrecognisable; some with slight fever, perhaps, and vomiting, and on the next day a return to health with no further trouble. Such cases are difficult if not impossible to diagnose, and it is only their frequent occurrence in epidemics that betrays their identity. They are important because mosquitoes may become infected from them, and transmit the severe types of the disease.

2. *Mild forms.*—These are slightly more marked than the former. There is a single paroxysm of fever, lasting 2 to 4 days, then a rapid fall, and restoration to health. Distinct jaundice, however, may be noticeable, and if the urine be examined carefully, albumin is generally present after the second day. Headache, eye pains and vomiting may also occur.

3. *Severe forms (the ordinary form).*—The onset is usually sudden, a rigor or feeling of chilliness down the back ushering in the disease. The temperature rises rapidly to 103° F. to 104° F., and the patient looks ill. Further, there are pains in the back and limbs, severe frontal headache, with flushing of the skin of the face, and injection of the eyes (ferret eye) and photophobia. The tongue is sharp-pointed with bright red edges, and thickly furred dorsum, appetite is lost, and bilious vomiting may appear quite early. Epigastric pain has been said to be pathognomonic. Jaundice—which has given the

characteristic name to yellow fever—appears, according to Sternberg, on the third day of the disease; but it may sometimes be noted even earlier. Albuminuria appears after 48 hours, and continues to increase until very large degrees may be present.

After remaining high for 3 or 4 days, the temperature falls suddenly to 100° F. or lower, and this lull is known as the remission. In the mild type of case it does not rise again, but in the severe case, after remaining low for some hours to a day, there is a febrile exacerbation, and this occasions the second paroxysm or relapse. The pulse, which in the early stages of the disease was full and bounding, 120 or so per minute, gradually decreases as the time of the remission approaches, and remains low, 40 or 50 per minute, when the temperature rises the second time (Faget's sign). This when well marked is one of the surest tests of yellow fever.

During the second paroxysm most of the symptoms of the first return. Vomiting becomes marked, with much tenderness in the epigastrium; the thirst is excessive with great prostration, the tongue becomes dry and cracked, and hæmorrhages may appear on different parts of the body. The temperature may eventually fall after 2 or 3 days and the patient recover, or further symptoms of great gravity appear—black vomit, melæna, suppression of urine, delirium, coma, convulsions and death.

4. *Malignant forms.*—In this type, the symptoms proper to the remission stage make their appearance within the first 3 or 4 days. The temperature may reach 106° F. Violent vomiting followed by black vomit occurs early, and symptoms referable to the nervous system are apparent—subsultus tendinum, hiccough, tremors and delirium. Often profuse hæmorrhages, as in black smallpox, take place under the skin and the patient quickly dies, overcome by the severe toxæmia.

In yellow fever, the blood is not characteristic. The red corpuscles are not reduced; the whites vary between 7000 to 15,000 per c.mm. The polymorphonuclears are in excess, and there is no relative increase of the large mononuclears.

Complications and Sequelæ.—Boils, abscesses, dysentery and general debility may follow an attack, but, as a rule, once convalescence has set in, recovery is rapid.

Diagnosis.—The disease most readily mistaken for yellow fever is malaria—the so-called bilious remittent type. Careful blood examinations must therefore be made for malarial parasites, and quinine should not be given until this is done. The blood in malaria shows a relative increase of the large mononuclears, an important point in differentiating the two diseases. The occurrence of many cases simultaneously points to yellow fever. Dengue has also been mistaken for yellow fever. It may be recognised by the preliminary rash, leucopenia, and the absence of albuminuria.

Prognosis.—The death-rate varies in different epidemics from 30 to 80 per cent. It must always be considered a deadly disease; features such as a high degree of albuminuria, marked diminution of urine, black vomit and disturbances of the nervous system, are always of grave omen.

Treatment.—By adopting segregation of infected individuals, by preventing mosquitoes obtaining access to them, and at the same time by destroying mosquitoes (*Aedes*) both in their adult and larval stages, the Americans cleared Havana, Panama, Colon and other infected areas completely, and

stamped out the disease in many of its old endemic haunts. There is no specific drug for the disease, the treatment of which is mainly symptomatic. Sternberg proposed the following mixture: Sodii bicarb., grs. 150; hydrarg. perchlor., gr. $\frac{1}{2}$; aquam ad oz. 40—3 tablespoonful doses every hour.

This is said to prevent vomiting and also suppression of urine. It often fails, however, to ward off a fatal termination.

For vomiting in addition, a mustard leaf may be applied to the epigastrium, or sips of iced champagne given; chloroform, 2 or 3 drops, a drop of creosote, tinct. iodi, 2 drops may be tried. Opium should not be given. Heart failure is an indication for stimulants—alcohol, strychnine, etc. For suppression of urine, hot fomentations over the back and injections of 15 grains of urea are valuable. Diet should be of the simplest nature; very little of anything should be given at first, then milk and lime water; toast water, raisin tea and barley water may be cautiously tried. The diet must not be increased during the remission, as this is a dangerous time. After the temperature has been normal for 4 days after the second paroxysm, a gradual increase in the food may be begun—chicken broth, custard puddings, etc.

After convalescence a change of air is advisable—a voyage home to England or to some other place, if possible. One attack confers immunity almost without exception, so there is no danger in returning to the endemic haunts of the disease.

Hindle has recently shown that a vaccine consisting of carbolised or formalinised livers of monkeys (*Macacus rhesus*) which have died of the disease will confer on these animals an immunity against very large doses of virus. The application of this vaccine towards the protection of human beings is now in progress.

PHLEBOTOMUS FEVER

Synonyms.—Pappataci Fever; Three-day Fever; Sand-fly Fever; Simple Continued Fever; Pym's Fever.

Definition.—An acute specific fever due to a filterable virus which lasts about 3 days and is spread by sand-flies, *Phlebotomus papatasi*.

Ætiology.—The disease is common in the Mediterranean basin, in India, Mesopotamia, Persia, etc. It would appear to be commonest amongst the white races, though natives are also affected. No germ is known, the disease being due to one of the filterable virus group of diseases. The virus can be filtered through an F. Pasteur-Chamberland candle, and is present in the peripheral blood on the first and second days of the disease. Sand-flies (*P. papatasi*) that suck the infected blood on those days become infected, and a development of some sort takes place in their bodies, the flies themselves becoming infective 7 days after biting. (Compare Yellow Fever and Dengue.) Once a fly is infected it probably remains so for the rest of its life. Experimentally, blood taken on the first and second days will produce the disease by inoculation, and volunteers have also been bitten by infective flies, and acquired the disease. The incubation period of the experimental cases varied from 3 to 7 days.

Pathology.—Of this little is known, as cases rarely, if ever, die.

Symptoms.—Prodromal symptoms may usher in the disease—malaise, vague pains, discomfort and weariness. The onset is sudden, with chilly feelings, frontal headache and lumbar pains. The temperature rises rapidly, reaching 104° F. or 105° F. at the end of 24 hours. The mouth and throat are congested. There is no vomiting as a rule, but there may be diarrhoea. Pains in the joints and cramps are not uncommon. The skin is usually dry, but in some cases there is sweating. The blood shows a leucopenia of 4000 or 5000 whites per cubic millimetre. In 36 to 48 hours the temperature falls slowly to normal. With the fall there may be epistaxis, more rarely sweating, vomiting and diarrhoea. After the temperature falls all the symptoms abate. Convalescence is usually prolonged.

An afebrile variety is described. Abortive forms are also seen.

Diagnosis.—This is difficult in the first instance. The disease closely resembles influenza. The blood should be examined to differentiate it from malaria.

Prognosis.—This is good. Apart from the temporary discomfort, there is nothing to fear. One attack is supposed to confer immunity. The disease, *per se*, is not fatal.

Treatment.—Destruction of sand-flies and avoidance, as far as possible, of their bites speak for themselves. There is no specific treatment. The patient should be kept in bed till the temperature falls. Aspirin and phenacetin may be given to relieve the headache and general discomfort.

DENGUE

Definition.—Dengue is an acute specific fever, due to a filterable virus, and spread from man to man by the agency of a mosquito (*Aedes ægypti* (formerly *Stegomyia calopus*). There are generally two febrile paroxysms, with an intermission or remission without jaundice, albuminuria and hæmorrhages, but with a marked leucopenia and with a pulse which varies directly with the temperature.

Ætiology.—The disease occurs universally throughout the tropics and subtropics, and is often epidemic. All ages and sexes are liable. No definite germ has yet been isolated. The virus is filterable, the filtrate, as, also, the unfiltered blood if taken on the third or fourth days of the illness, causing the disease when inoculated into suitable individuals. The mosquito acts as an intermediate host, the virus undergoing development in the insect before it is capable of being transmitted back to man.

Pathology.—The disease is rarely fatal. Edema and congestion of the lungs have, however, been noted in cases that have died in Calcutta. There is nothing specially characteristic on post-mortem examination.

Symptoms.—Prodromata—feelings of general malaise, with pains in the fingers and limbs generally—may usher in the fever. More commonly, the onset is sudden with a rapidly rising temperature, headache and aching in the eyeballs. The limbs and joints then become stiff and very painful. The pains are often so severe that the name of break-bone fever has been given to the disease. The skin shows a general flushing, with congestion of the mouth and throat; this erythematous condition forms the so-called initial rash. If the case become severe, all the symptoms are intensified, the temperature reaching 105° F. or 106° F., and owing to the pains move-

ments are impossible, the patient being bedridden. Vomiting is not infrequent. After 3 or 4 days, the temperature falls by crisis, diarrhoea, sweating and epistaxis often accompanying the fall. All the symptoms then improve, and the stage of remission is reached. After feeling quite well for a day or two, so well in fact that the patient may have got up and gone out, the temperature rises again (the third stage), this time associated with a measly roseolar rash, best seen on the hands, wrists, elbows and knees. The spots disappear on pressure, and do not become petechial. The pains are severe in this stage, but after lasting a few days the temperature finally falls, the rash fades and convalescence begins. The blood shows a leucopenia.

Complications and Sequelæ.—The pains may persist with a considerable degree of crippling and lameness. General debility, often combined with sleeplessness, is common. Boils are also sometimes troublesome. One attack usually confers immunity, though second and third ones have been recorded. It is now generally considered that the seven-day fever of Calcutta described by Rogers is a variety of dengue.

Diagnosis.—Measles, German measles, scarlet fever, influenza, rheumatic fever, secondary syphilis and malaria may all quite easily be mistaken for dengue. Yellow fever is distinguished from it by the presence of jaundice and albuminuria. The rapid occurrence of other cases and the special pains greatly help the diagnosis.

Prognosis.—This is good, the death-rate being very small. Charles mentions a pernicious form in Calcutta with oedema of the lungs, and finally death with cyanosis. In old people and in children, especially if debilitated by other diseases, an attack of dengue may prove fatal. Different epidemics vary greatly in their virulence.

Treatment.—Destruction of mosquitoes will remove the disease. Rid the town of *Culex fatigans* and *Aedes aegypti* and the disease must disappear. The abolition of mosquitoes in Port Said freed that port from dengue (E. H. Ross). Every one in the tropics should sleep in a mosquito net. This considerably diminishes the chance of infection. The patient should be put to bed and kept there for 10 days, namely, until the terminal eruption has disappeared. The diet should be light and of a fluid nature. A.B.C. liniment may be used to rub on the limbs and joints for the pains. Morphine may even be required. Purgatives must be avoided, because of the movements they entail. Ice relieves the headaches.

When convalescence is established, gentle massage and electricity will be found useful for the limbs. The food should be good; a voyage should be taken if possible for change of air. Tonics such as Easton's syrup are also indicated.

SPOTTED FEVER OF THE ROCKY MOUNTAINS

Synonyms.—Blue Disease; Black Fever; Spotted Fever.

Definition.—A fever of the typhus group, spread by a tick, *Dermacentor venustus*, and not by lice.

Ætiology.—The disease is more or less strictly limited to some of the States of America, Idaho and Montana especially. All ages and both sexes

may suffer. The germ has not yet been isolated, though rickettsia bodies have been found. It has been abundantly proved that the cause of infection is carried and spread by a tick, *D. venustus*, a common parasite in the valleys where the disease occurs.

Pathology.—The signs of a severe toxæmia, as in typhus, are present, such as fatty heart, liver and kidneys, enlarged congested spleen, hypostatic congestion of the lungs.

Symptoms.—The temperature, which rises to 104° or 105° F., or higher, comes on somewhat insidiously, after a variable incubation period of from 7 to 14 days. The usual loss of appetite, headache, malaise, as seen in other fevers, are present. On the fourth to the seventh day the characteristic eruption appears, first on the wrists and then extends to the limbs and trunk, the face remaining free. The spots are rose-coloured, pink or red, not unlike the ordinary typhus rash, some of them becoming petechial from extravasation of blood. Some remain discrete, others become confluent. The rash gradually fades as the fever subsides, at the fourteenth day or a little later. The bowels are usually constipated, vomiting is common, congestion of the lungs or pneumonia may appear and the urine generally shows albumin. The leucocytes are increased.

Complications and Sequelæ.—Gangrene of the fingers and toes, pneumonia, suppuration of the parotid gland, femoral thrombosis and otitis media may follow the disease.

Diagnosis.—This must be made from ordinary typhus. The geographical distribution gives one the clue to the diagnosis.

Prognosis.—This varies considerably, the mortality being much higher in Montana (90 per cent.) than in Idaho, where it is only 5 per cent. (Ricketts). It must always be considered a grave disease.

Treatment.—Where possible the tick should be exterminated. In the infected areas small mammals, such as ground squirrels, and woodchucks, have been destroyed, because the larval and nymphal forms of the ticks develop and live on these animals. Systematic dipping of goats and sheep should be carried out, as these animals act as hosts. The symptoms must be treated on general principles as in other fevers. Serum treatment, the serum being obtained by passing the virus through guinea-pigs and then inoculating horses, such as has been tried by Nicolle and Blaizot for typhus fever, might also prove useful.

TSUTSUGAMUSHI FEVER

Synonyms.—Japanese River Fever; Flood Fever; Kedani Disease; Akamushi Disease; Shimamushi Fever.

Definition.—An acute infectious disease, occurring in the island of Nippon, Japan, caused by the bite of a trombidium, and associated with fever, lymphangitis, and an erythematous eruption.

Ætiology.—The disease is strictly limited to one or two areas on the banks of some of the rivers on the west coast of the principal island of Japan. All ages are liable. The parasitic cause is still unknown, but the virus is spread by a trombidium, now named the *Leptotrombidium akamushi*, a mite which is common in the Yamagata district in which the disease is endemic.

The mature form or prosopon produces larvæ (mites) which feed on mammals, chiefly field mice, and thus man may become infected. (Compare the harvest bug or mite in England.)

Pathology.—Few post-mortem examinations have been recorded in English literature. Kawakami's cases showed hypostatic congestion of the lungs, bronchitis, myocardial softening, enlargement of the spleen, injection of the mucosa round the ileo-cæcal valve and general enlargement of the mesenteric lymph glands.

Symptoms.—The bite of an infected mite gives rise to a small, round, black eschar or scab, most commonly found near the genitals or the axillæ. An incubation period then supervenes of 5 to 12 days, after which there is a rise of temperature, often ushered in by severe rigors. The lymphatics, draining the area of the bite, then become inflamed, with enlargement of the proximal glands. The pyrexia continues high, and on the sixth or seventh day the exanthem appears, viz., an eruption of large, irregular, dark-red papules, or small hæmorrhages, first appearing on the face, and spreading to the fore-arms, legs and trunk. This lasts for a few days, 4 to 7 as a rule. After lasting on an average from 14 to 21 days, the temperature falls and convalescence begins. Conjunctivitis, with signs of bronchial irritation, profuse sweating, spongy gums and constipation have been noted. During the course of the disease the scab falls off and a small ulcer is seen in its place.

Diagnosis.—In an infected area this is easy, the scab of the bite, with the other symptoms, can hardly be mistaken for anything else.

Prognosis.—The mortality is high: 20 to 50 per cent.

Treatment.—Infection should be avoided as far as possible. Treatment is purely symptomatic, the patient's strength being conserved as far as possible.

OROYA FEVER.

Synonyms.—La Maladie de Carrion; Carrion's Disease.

Definition.—An acute infectious disease of doubtful ætiology, limited to the western slopes of the Peruvian Andes, associated with peculiar rod-shaped bodies in the red blood corpuscles, *Bartonella bacilliformis* or Barton's bodies.

Ætiology.—The members of the Harvard School of Tropical Medicine, who studied the disease in Lima in 1913 under Strong, finally came to the conclusion that the bodies mentioned above were akin to the protozoa and caused the disease. How they are transmitted from one person to another is unknown. An insect vector is suspected. Any one living in, or staying for a time in, the endemic area is liable to acquire the disease. Both sexes are liable and children may be attacked. The Commission also concluded that *Verruga peruviana* is a separate disease and not a stage of Oroya fever. Lately, however, Noguchi, in experimental work on these two diseases, has shown again that they are connected with each other, and, according to him, the verruga eruption is only a phase of the oroya fever.

Pathology.—The spleen is usually enlarged and large swollen endothelial cells, containing rod-shaped bodies, are seen. The lymphatic glands also show similar cells. The liver shows toxic degeneration, with areas of necrosis. Lesions of an ulcerative nature have also been described in the large intestine.

Symptoms.—The incubation period is said to be 21 days. After this the onset is fairly rapid, with malaise, headache, pains and the usual signs of fever. The pains are usually very marked and are sometimes the first symptom noted. They may affect any part of the body, the bones frequently being involved and very tender. The temperature rises and runs an irregular course somewhat similar to that of a paratyphoid infection. It gradually falls in the fourth week. Severe cases generally die; there are no skin eruptions apart from the verrugas. The superficial and lymphatic glands are enlarged and palpable. Anæmia rapidly develops, the red blood corpuscles falling to as low as 1,000,000 or even lower. The leucocytes are said to be increased 20,000 per c.mm. or upwards. Barton's bodies are very numerous in the red cells in bad cases, but are also seen in mild cases. In fatal cases the patient sinks into a comatose condition, the temperature falls to normal or sub-normal.

Diagnosis.—This has to be made specially from the paratyphoids. All fevers occurring in the endemic areas should be treated as suspect until proved to be due to some other cause. Malaria and tuberculosis have been mistaken for this disease. Rheumatic may simulate it closely as regards the pain and sweating; in Oroya fever, however, the joints are rarely involved, and anti-rheumatic treatment has no effect.

Prognosis.—This is good in mild cases, bad in the severe kind. The mortality among undoubted cases of Oroya fever has been stated by Strong to be 30 to 40 per cent. In some epidemics it has even been higher than this.

Treatment.—There is no specific treatment; the patient ought to be kept strictly in bed, and the fever dealt with on general principles. A diet similar to that employed in typhoid fever is indicated. As the temperature falls, the diet may be gradually increased. From a prophylactic point of view one should avoid the endemic areas where possible, or at any rate should not spend the night in them. Little, however, can be done as regards prophylaxis until the exact aetiology of the disease has been worked out.

VERRUGA PERUVIANA

Ætiology.—According to some, this condition is only a phase or stage of Oroya fever, while others believe it to be a separate disease. Strong and the Harvard Commission, who believe in the duality of the two conditions, have transmitted the disease to monkeys by scarifying their skin and rubbing in verruga material. The lesion remains local. Noguchi's recent work, however, does not support the dual view and tends to show that verruga peruviana, as previously believed, is only a phase of Oroya fever. Barton's bodies have been found in it also. The eruption in some ways resembles yaws, but the *Treponema pertenue* is absent, the Wassermann reaction is negative, and salvarsan and similar drugs have no effect upon it.

Pathology.—The pathological changes found are those of an infective granuloma. The endothelium of the lymphatics and blood vessels proliferates. Plasma cells, granulation-tissue cells and fibroblasts appear, these being contained in a delicate reticulum or stroma of fibrous tissue. In the early stages there are many newly-formed blood vessels which make the tumours very vascular, so that they bleed easily. In the later stages the

amount of connective tissue increases, and the appearance of a fibrosarcoma may be simulated.

Symptoms.—The incubation period varies from 14 to 21 days, then pains of a rheumatic nature develop in the limbs and joints and a moderate temperature appears. Following this period of invasion the second stage appears—this consists of the *eruption of the tubercles* or *papules* which are usually described as being of a miliary or nodular nature. At first these are slightly raised, red spots, which later become dark-red or dusky blue, and then later still, in the nodular variety, take on the form of warty excrescences. The eruption may come out over the whole body, though the face, neck and limbs are the favourite sites—their number varies, from a dozen in the nodular variety, to hundreds in the miliary type. The size also varies, many of the nodular ones reaching the size of a chestnut and often ulcerating (the mulaire lesion) while the miliary ones are about the size of a small pea—they bleed easily, their apices often being dotted with little black marks. The mucous membranes are attacked as well as the skin, and even the internal organs; if in the nose they may cause bleeding, and if in the larynx, cough and hoarseness and sometimes sudden death. Successive crops continue to come out, each preceded by a fresh rise of temperature.

The third stage consists of *desiccation of the eruption* as a result of shrinkage of the tubercles, or by ulceration. The larger ones usually ulcerate and bleed very freely, resembling malignant masses. Finally they scab, and when this drops off a cicatrix remains at the site. If no ulceration has taken place, little or no scar is left. The condition is very rarely fatal, and there is no marked anæmia.

Diagnosis.—The warty excrescences are easily recognised and should not be mistaken for other diseases.

Prognosis.—As already mentioned this is good, fatal results being rare.

Treatment.—No specific treatment is known. Salvarsan has no effect upon the lesions. When the nodules ulcerate they must be kept clean by antiseptics and excessive hæmorrhage suitably combated.

G. CARMICHAEL LOW.

SECTION III

TROPICAL DISEASES OF DOUBTFUL OR UNKNOWN NATURE

LATAH

Definition.—A form of cerebral neurosis, in which the patients make involuntary movements and incoherently utter sounds or words (Scheube).

Ætiology.—The condition has been found in Java, the Philippines, Burma and Siam. Natives are affected, principally young women. Heredity may play a part. No exciting cause is known.

Pathology.—There are no records of any post-mortem examinations.

Symptoms.—The movements and incoherent sounds are involuntary, the patient being unable to restrain them. The reflexes may be increased, and people affected take fright easily.

Diagnosis.—The disease must be distinguished from ordinary mental and nervous disorders.

Prognosis.—The disease may persist for years, and appears to be incurable.

Treatment.—None is known. Suggestion treatment might be tried.

KUBISAGARI

Definition.—A disease associated with dimness of sight, diplopia and paresis of the cervical muscles (Miura).

Ætiology.—The condition is found endemically in parts of Japan. It attacks the agricultural natives of any age or sex, and house epidemics have been recorded. The cause is unknown.

Pathology.—This has not been established.

Symptoms.—Depression is usually present, followed by dimness of vision, often accompanied by ptosis; paresis of the cervical muscles, muscles of the trunk, etc., is also common. Owing to the implication of the cervical muscles the head hangs down, whence the name of the disease. The symptoms intermit, intervals of freedom alternating with new attacks.

Diagnosis.—It must be distinguished from other forms of paralysis.

Prognosis.—The disease is said never to end fatally.

Treatment.—Miura recommends potassium iodide and arsenic.

AINHUM

Definition.—A disease of the toes, characterised by a ring-shaped constriction, which finally causes amputation of the toe affected.

Ætiology.—The disease is principally found on the West Coast of Africa, but it has also been seen in Brazil, British Guiana, the West Indies, the southern states of the U.S.A. and in India. Negroes and Hindoos are attacked. The cause is obscure. A trophic origin has been suggested; also injuries, such as cuts from grass, jiggers, etc.

Pathology.—The constricting ring is formed of fibrous tissue. An increase in the adipose tissue of the part has been noted by some, a thickening of the epidermis by others. Natives are very prone to fibrous tissue formation, *e.g.* keloid.

Symptoms.—The little toe is most usually affected. The disease commences by a groove or furrow, which first appears in the digito-plantar fold; this gradually deepens and spreads round the portion of the toe distal to the swelling. The change advances until the band is so narrow that the toe hangs by a thin pedicle. Finally the organ may drop off spontaneously, be torn off, or be purposely cut off by the patient. The course of the malady is slow—usually several years.

Prognosis.—There is no danger to life.

Treatment.—The toe should be removed by the knife, or by a silk ligature. Da Silva proposes vertical incisions through the constricting band in the early stages.

GOUNDOU

Synonyms.—Anakhre; Gros Nez; Dog Nose.

Definition.—Symmetrical bony excrescences, occurring on both sides of the nose.

Ætiology.—(a) The disease occurs on the West Coast of Africa—on the Gold Coast, Ivory Coast and in Sierra Leone. It is apparently confined to negroes—both children and adults. Recently the author has seen the photograph of a Dyak child from Sarawak suffering from the same or a similar condition. Chalmers thinks the condition follows yaws, others have suggested nasal myiasis.

Pathology.—The tumours consist of spongy bone covered by a thin shell of compact bone, and are oval in shape, and may eventually attain the size of a hen's egg. They are supposed to grow from the nasal process of the superior maxilla.

Symptoms.—Pain is complained of at first, often with severe headaches, and there may be a nasal discharge with pus and blood. These symptoms ultimately disappear, but the swellings continue to enlarge slowly and progressively.

Diagnosis.—The characteristic swellings can hardly be mistaken for any thing else.

Prognosis.—The condition is not dangerous to life.

Treatment.—Chiselling away the bone is the treatment usually recommended.

GANGOSA

Synonym.—Destructive Ulcerating Rhino-pharyngitis.

Definition.—A destructive ulcerative process attacking and destroying the nose, mouth and pharynx.

Ætiology.—The condition has been described in the West Indies, Fiji, Guam, etc. Natives are attacked—children and adults alike.

Tubercle, leprosy, syphilis and yaws have all been suggested as the cause. Others believe it to be a disease *sui generis*. A somewhat similar condition follows American dermal Leishmaniasis, and the possibility of some of these cases being Leishmanial should always be borne in mind, and a search made for such parasites.

Pathology.—The disease generally begins as a small ulcer of the palate, gradually spreading, until it ultimately destroys most of the nose, the pharynx, soft palate and mouth.

Symptoms.—As the ulceration spreads pain is complained of, and a constant discharge oozes out of the lesions, giving the breath a horribly foul odour. The mutilation may be extreme and destroy most of the face.

Diagnosis.—This must be made especially from Leishmaniasis, and from syphilis, leprosy and yaws.

Prognosis.—Sometimes the disease stops of its own accord, more frequently it progresses, ultimately killing the patient by general exhaustion and sepsis.

Treatment.—Salvarsan or some of its products should be tried, in case syphilis or yaws may be present. Antimony, on the assumption of a Leishmanial origin, should also be given a trial.

BIG HEEL

Synonym.—Endemic Hypertrophy of the Os Calcis.

Definition.—A peculiar hypertrophic condition of the os calcis.

Ætiology.—This has not yet been established. The condition occurs in natives of the West Coast of Africa, chiefly on the Gold Coast.

Symptoms.—The disease is ushered in with fever, followed by pain and tenderness in the heel, with swelling of the os calcis of one or both feet. Cold and damp are apt to produce an increase in the symptoms. Walking is hindered. The condition may become chronic, permanent thickening of the bone resulting.

Treatment.—If the enlargement be excessive, removal of some of the hypertrophic bone may be attempted.

MOSSY FOOT

Thomas described this condition some years ago in Manaos, Brazil. He considered it had something to do with elephantiasis. Recently Castellani saw a condition, called Central American Mossy Foot, in Costa Rica and Guatemala. His case showed the foot covered with granulomatous nodules and masses covered by dirty yellow crusts. No sinuses or sclerotia were

present, this distinguishing it from Madura foot. It was not Yaws nor Verruga. He thinks it similar to the cases described by Thomas. Treatment is very unsatisfactory. X-rays might be tried.

CHAPPA

Definition.—A peculiar affection of the joints associated with nodules in the subcutaneous tissues, which finally ulcerate.

Ætiology.—The disease was described by Read in Southern Nigeria. Natives only are attacked, as far as is known.

The causative agent has eluded detection.

Pathology.—This is not yet entirely known. Nodules, as large as a pigeon's egg, form in the subcutaneous tissues, with ultimately complete destruction of the joints—the bones are also attacked.

Symptoms.—The disease, according to Read, begins with severe pains in the limbs, muscles and joints. After a time the pains decrease, but some of the joints swell, and fluctuation occurs. At this time nodules appear in the tissues, and the skin over them breaks down with resulting ulcer formation. The ulcers have no tendency to heal, but may remain for years.

Diagnosis.—The disease may be a late stage of yaws; some of the nodules might be onchocerca tumours (see p. 337). Tropical ulcer is also possible.

Prognosis.—This is bad.

Treatment.—Read tried mercury and iodides without effect. Scraping is indicated. Salvarsan and its derivatives should be given a good trial, on the chance of the infection being spirochætal in nature.

JUXTA-ARTICULAR NODES

Definition.—A nodular condition occurring around the joints.

Ætiology.—Such tumours have been described in Africa, on the West Coast and equatorial regions, also in Java and Siam.

Pathology.—The constitution of the nodes seems to be of a fibrous nature, but more work is required to determine their exact composition.

Symptoms.—The tumours usually appear in the vicinity of one or other of the joints. At first they are small, the size of peas, but later as they grow may be as large as a pigeon's egg. They are round or oval, and very hard to the touch. There are generally four or five or more, and they may have a symmetrical distribution. Rarely they disappear spontaneously, more commonly they increase gradually in size, but very slowly; at other times they remain stationary for long periods of time.

Diagnosis.—The diagnosis lies between ordinary rheumatic nodules and onchocerca tumours. A tumour may be excised and sectioned. They may be of rheumatic origin, but are not quite like the ordinary rheumatic nodules. An onchocerca tumour when needled is found to contain fluid, and when opened is seen to be loculated, with the filariæ in situ and many embryos in the fluid.

Prognosis.—This is quite favourable as regards life, and in many instances the nodules cause little or no trouble.

Treatment.—The best way of dealing with the nodules is to excise them; this can be more easily done, of course, when they are small.

ONYALAI

Definition.—A vesicular condition of the buccal mucosa, associated with renal hæmaturia.

Ætiology.—The disease is met with in Portuguese West Africa, and on the Lualaba river. Natives are attacked. No cause is known.

Pathology.—No proper autopsies have yet been made.

Symptoms.—The disease is usually ushered in by a febrile disturbance, and after some little time an eruption of small blebs or vesicles appears on the buccal mucosa and the hard palate. Some of the blebs show umbilication—their contents consist of blood. Blood is also present in the urine.

Diagnosis.—This has to be made from purpura, pemphigus, small-pox, etc.

Prognosis.—Natives are said to dread the disease. Most cases are said, however, to recover in from a week to 10 days.

Treatment.—None is known. Calcium lactate might be tried.

EPIDEMIC GANGRENOUS RECTITIS

Definition.—A form of rapidly spreading phagedæna which starts in the neighbourhood of the anus and spreads to the rectum.

Ætiology.—The disease has been reported from Venezuela and the Guianas. Possibly the condition is only a gangrenous form of one or other of the dysenteries.

Symptoms.—The disease starts with itching at the anus, followed by the passage of blood and mucus, great tenesmus, thirst and fever. Gangrene then sets in, and the patient quickly dies.

Treatment.—Local native treatment consists of enemata of lemon juice and rum, or a decoction of the stalks and leaves of a South American plant, *Spigelia anthelmintica*.

CLIMATIC BUBO

Definition.—A febrile condition associated with glandular groin enlargements, which tend to become chronic and indolent, some ending in suppuration.

Ætiology.—The condition is specially common on the East Coast of Africa. It also occurs on the West Coast of Africa, Hong-Kong, China, Japan and in the Straits of Malacca. Males apparently are alone affected. Recent work tends to show that, though not venereal in the ordinary sense, the disease is nevertheless acquired from sexual connection with black women. A history of such connection is always obtainable. The germ is unknown. Puncture of the glands usually gives negative results; when suppuration takes place the ordinary pyogenic cocci are present.

Pathology.—Section of the affected glands only shows a chronic adenitis. Resolution takes place spontaneously, but is very slow. Suppuration is a secondary feature due to the invasion of ordinary cocci. There are no signs of any lesions on the penis.

Symptoms.—The condition occurs a variable time after connection.

The temperature, of a remittent type, remains up for a week or longer. The glands then start to enlarge and become painful, interfering with walking. One or both sides may be affected. The size of the glands varies, some attaining the size of a pigeon's egg, others that of a hen's. They are very chronic and indolent, showing little or no tendency to disappear. The temperature finally falls, and if the patient keeps quiet the adenitis gradually resolves, but some slight thickening often remains. The glands are hard to the touch and do not show signs of fluctuation unless suppuration has occurred.

Diagnosis.—Some of the glands, the hard type with no fluctuation, closely resemble those of *filariasis*. Other signs of filarial disease elsewhere will help in the diagnosis. As a rule also, unless a definite attack of filarial lymphangitis is present, there is no temperature with these glands. Climatic bubos have nothing to do with plague, and are not *Pestis minor*. The other ordinary venereal causes must be excluded before arriving at the diagnosis of climatic bubo, as must also scratches, abrasions or foci of infection about the legs or feet.

Treatment.—If the glands be small and resolving they are best left alone. The patient should walk as little as possible, as exercise of any sort generally aggravates them and delays their absorption. If suppurations have taken place, aspiration of the pus should first be tried, instead of laying the glands open, as then secondary infection results and healing may be long delayed. Extensive removal of the glands is dangerous, as elephantiasis of the thigh and leg may follow, if there be too much interference with the lymphatic system. After the temperature and acute signs have quietened down, the glands may be painted with linimentum iodi, and potassium iodide may be given internally to promote their absorption. If chronic and not resolving protein shock may be tried. In such a case 2 intravenous injections of ordinary T.A.B. vaccine—100 million for the first dose and 200 for the second—had a most marked effect upon the condition.

FEVERS OF DOUBTFUL OR UNKNOWN ÆTIOLOGY

As diagnostic methods improve, many of the irregular fevers which used to be variously classified as pyrexia of unknown origin (P.U.O.) have disappeared; but even so, there are still more or less definite conditions which cannot be explained satisfactorily on our present knowledge.

Simple continued fever.—Some of these cases may in reality be sand-fly fever or mild typhoids or paratyphoids. The extended use of Widal's reaction for the enterica group should certainly eliminate some of them.

Seven-day fever.—Rogers has described this fever in Calcutta, and it is found in other ports as well. It is characterised by a sudden invasion, with headache and pains in the back. The temperature chart shows a saddleback type of fever, and the pulse is slow as compared with the temperature. It lasts 6 or 7 days. Some authorities consider it a form of dengue. Quite recently Japanese observers have isolated a spirochæte from the 7-day fever in Japan. This is a *Leptospira* and has been named the *Leptospira hebdomadis*. It is quite possible all these are varieties of dengue.

Low fever.—An evening rise of temperature to 99° F. or 100° F. or a little higher is not uncommon in people who have resided abroad. None of the definite causes of slight fever, such as helminthic infections, are to be found. Possibly some are due to some hidden focus of tubercle, others to syphilis or to early malignant disease.

Double continued fever.—Manson describes cases of this fever in Amoy, China. There are waves of fever with apyrexial intervals. The charts somewhat closely resemble undulant fever. A similar type of fever has been met with in cases from the West Coast of Africa. They seem to be akin to, though perhaps not absolutely identical with, undulant fever. Some may be para-undulant fever infections.

Hyperpyrexial fever.—One or two examples of this peculiar condition have been reported from the West Coast of Africa. The fever is associated with a very high temperature—107° F. or higher, and this continues for 3 weeks or longer. If recovery take place the temperature then drops and ultimately the patient gets well. Many cases, however, die. The spleen and liver are not enlarged. Quinine is useless, and the only treatment is cold baths and cold sponging with ice water.

G. CARMICHAEL LOW.

SECTION IV

DISEASES DUE TO METAZOA

1. DISEASES DUE TO TREMATODES OR FLUKES—DISTOMIASIS

PARAMPHISTOMIASIS

Definition.—An invasion of man with trematode parasites of the family *Paramphistomidæ*. Two of these parasites are known. *Watsonius watsoni* (*Cladorchis watsoni*).—L. 8-10 mm. \times 4-5 mm.; Ova, 120-130 μ \times 75-80 μ . The parasite has a reddish-yellow colour when fresh and inhabits the duodenum and upper part of the small intestine.

Gastrodiscus hominis.—L. 5-8 mm. \times 3-4 mm.; Ova, 150 μ \times 72 μ . The parasite has a large posterior disc by which it attaches itself to the mucous membrane of the bowel; it occurs in the cæcum and colon.

Symptoms.—Diarrhœa, with loose bilious stools, containing many of the adult parasites, is the outstanding symptom of the former species; severe infections of the latter produce some intestinal disturbance, with diarrhœa.

Treatment.—Thymol followed by saline purgatives; or eucalyptus, castor oil, chloroform mixture. (See Treatment of Ankylostomiasis.)

FASCIOLIASIS

Definition.—An invasion of man and other animals with flukes of the family *Fasciolidæ*. Several of these are known.

Fasciola hepatica (*Distoma hepaticum*)—the common liver fluke—L. 20-30 mm. \times 8-13 mm.; Ova, 130-145 μ \times 70-90 μ . Oval and operculated. These parasites normally inhabit the bile-ducts of sheep and other animals. They undergo their developmental changes outside the body in snails (*Limnæa truncatula*) and finally disseminate the infection by the cercariæ which have left the snail and become encysted on grass stems.

Symptoms.—Man is not often infected. In some of the reported cases, mild infections evidently, there were no symptoms, the diagnosis being made by finding the ova in the stools. In sheep, the parasite produces a disease named liver rot or sheep rot. The infected animals become emaciated and many die.

Treatment.—Ordinary anthelmintic drugs do not reach parasites in the liver; antimonium tartaratum might be tried intravenously.

Fasciolopsis buskii (*Distoma crassum*; *Distoma buskii*)—L. 30–70 mm. \times 12–14 mm.; Ova, 120–130 μ \times 77–80 μ . This, the giant fluke, is found in China, Borneo, the Federated Malay States and other regions in the East; it inhabits the duodenum and other parts of the small intestine. Its intermediate host is supposed to be oysters or shrimps. Three other species have also been described in man.

Symptoms.—Dyspepsia, diarrhoea with pale stools, sometimes streaked with blood. Increasing anæmia, œdema, ascites, harsh, dry skin. The signs sometimes resemble those of enteric fever and the infection has been mistaken for that disease.

Diagnosis.—This is made by finding the characteristic ova in the stools.

Treatment.—Thymol, or eucalyptus mixture, etc., will get rid of the parasites.

PARAGONIMIASIS

Synonyms.—See p. 1119.

Definition.—An invasion of man with the lung fluke, a member of the *Trogloremidae* family.

Paragonimus westermanii (*Distoma ringeri*; *Distoma pulmonis*, etc.)—L. 8–10 mm. \times 4–6 mm.; Ova, 85–100 μ \times 50–70 μ . Oval and operculated. Paragonimiasis occurs endemically in the Far East, especially in Formosa, Japan, Korea, and China. Sporadic cases, originally infected elsewhere, are from time to time met with in Western countries. The parasites live for preference in burrows in the lungs, but may be found in other parts of the body; the ova are found in the sputum or fæces. They then enter water, where the miracidium emerges from the egg and enters a fresh-water snail, the *Melania libertina*. Here it forms a sporocyst, then rediæ, then cercariæ, the latter escaping and finding their way into fresh-water crabs—*Potamon obtusipes*, *Geothelphusa dehaanii* and *Eriocheir japonica*. Encystment takes place here in the gills, liver and muscles, where further developmental changes take place. Man becomes infected by eating the crabs, or possibly the cercariæ escape from the crab into the water, and so are ingested; or bore themselves indirectly through the skin.

Pathology.—The parasites in the lungs live in cysts with dense fibrous walls; the largest cysts are the size of a hazel-nut. Cysts communicate with the bronchi and contain material resembling anchovy sauce. They have also been found in the brain, liver, intestines, spleen, pancreas, etc. They may give rise to suppuration; they also cause ulceration of the intestine.

Symptoms.—These are divided into general, thoracic, abdominal and cerebral.

General.—General adenitis and skin ulcerations are present. Blame can only be laid at the door of the paragonimus when the parasite is found in the affected parts.

Thoracic.—See p. 1119.

Abdominal.—If ulceration of the intestinal mucosa have taken place, diarrhoea with blood and mucus in the fæces will be present (paragonimus dysentery).

Cerebral.—Epileptic fits, giddiness, headaches, loss of memory, insomnia and loss of vision have been described.

Diagnosis.—This is made by finding the ova in the sputum or in the fæces.

Prognosis.—This is not good, the infection remaining indefinitely; tubercle is also apt to be superadded. The brain cases are fatal.

Treatment.—None so far is known. Antimony tartrate intravenously ought certainly to be tried, in view of the success which has followed its use in schistosomiasis.

CLONORCHIASIS

Definition.—An invasion with trematode parasites of the family *Opisthorchiidæ*. *Clonorchis sinensis* (*Opisthorchis sinensis*; *Distoma sinense*). L. 10–20 mm. \times 2–5 mm.; Ova, 27–30 μ \times 15–17 μ . Oval-shaped with a well-marked operculum. The parasites live in the bile-ducts and gall-bladder. The ova escape in the fæces, where a miracidium emerges, which finds its way into a snail, probably *Melania libertina*. The cercariæ escape in due course from the tissues of the first intermediate host and find their way into a second one, becoming encysted in the muscular tissues of some fresh-water fishes. Man or cats become infected by eating such infected fish in a raw condition.

Pathology.—Cystic dilatations and sinuses in the walls of the bile-ducts are produced by the parasites, irritative changes due to their presence causing localised fibrous changes as well (helminthic cirrhosis). The parenchymatous cells show fatty degeneration and necrotic changes. The liver becomes enlarged, with, perhaps, signs of chronic enteritis, ascites and œdema of the legs.

Symptoms.—Mild infections cause no symptoms; in more severe ones there is pain in the epigastrium and liver, with general wasting, diarrhœa and jaundice. The patient becomes feeble and cachectic and death may take place from exhaustion. Paralysis of the limbs has also been described.

Diagnosis.—The symptoms just described call for an examination of the fæces for ova; if found in large numbers, they probably are the real cause of the trouble.

Prognosis.—This is bad if the infection be severe; ascites and emaciation are serious omens.

Treatment.—None so far is known; as the parasites are lodged in the liver, ordinary anthelmintics do not reach them.

HETEROPHYIASIS

Definition.—Infection with flukes of the family *Heterophyiidæ*. Two genera occur in man:

Heterophyes heterophyes (*Cotylagonimus heterophyes*).—L. 2 mm. \times 1 mm.; Ova, 30 μ \times 17 μ . Oval, light brown colour.

Metagonimus yokagawai.—L. 1–2 mm. \times 0.4–0.7 mm.; Ova, 28 μ \times 16 μ . Elliptical, dark brown in colour, the shell membrane having a double contour.

The first stage is passed in a snail; the cercarial stage in fresh-water fish. This is the smallest fluke found in man.

Symptoms.—Both these species live in the small intestine and if present in large numbers produce diarrhœa with blood in the stools (heterophyes diarrhœa or dysentery).

Diagnosis.—This is reached in the ordinary stool examination, the eggs of the parasites being readily found in the fœces.

Treatment.—Eucalyptus, castor-oil and chloroform mixture is efficacious. In one of the author's cases over 250 adult worms were recovered after such treatment, and all signs of diarrhœa, etc., disappeared. The stool must be strained through fine muslin and searched carefully for the worms; otherwise, as they are so small, they are readily lost.

SCHISTOSOMIASIS

Synonym.—Bilharziasis.

Definition.—Invasion of man with members of the family *Schistosomida*. Three species occur in man—*Schistosoma hæmatobium*, *S. mansoni* and *S. japonicum*. The parasites live in the blood vessels—in the portal venous system—their eggs escaping by the urine or fœces; their external development takes place in different species of snails, from which the cercariæ escape into the water, passing directly into man through the skin, and finding their way to the blood vessels, where their complete development takes place.

Schistosoma hæmatobium (*Bilharzia hæmatobia*).—L. ♂ 12–14 mm. × 1 mm., 4 mm. round; ♀ 20 mm. × 0.25 mm.; Ova, 120–190 μ × 50–70 μ . Oval, no operculum, sharp terminal spine at end of egg; the intermediate host is a *Bulinus*—*B. dybowskyi*, *B. innesi*, *B. contortus*. The males are stout, with the sides rolled in to the ventral surface, forming the gynæcophoric canal in which the female lies. The integument is covered with fine tubercles. The females are much longer than the males and are thread-like or filariform in aspect. They can at once be distinguished from the presence of the two suckers of the trematodes.

Pathology.—When mature the adult females pass into the venous radicles of the bladder and rectum and deposit their ova, which, when deposited, cause a blockage, leading to engorgement and final rupture, with the escape of the ovum into the urine or fœces.

Two types of lesion are produced in the parts where the eggs are laid: (1) proliferative; (2) destructive, with ulceration; the irritation, plus the toxin excreted by the worms themselves, also causing considerable fibrosis—a change well seen in the liver. The bladder and rectum may show polypoidal or papillomatous growths, which bleed easily. Instead of such growths there may be smooth sandy patches, and in the rectum definite ulcers. The prostate is thickened and infiltrated with calcified eggs, the fibrous tissue being much increased. The seminal vesicles are also attacked, and the vagina and cervix in women. In bad cases the whole of the urinary tract is affected and also the rectum and considerable areas of the colon.

Symptoms.—Early general symptoms often precede the local ones: abdominal pain, enlargement and tenderness of the liver and spleen, pyrexia,

bronchitis, intense urticaria and diarrhoea, with a well-marked eosinophilia in the blood. A latent period then sets in, after which local symptoms appear. Hæmaturia with pain in the bladder, perineum and penis may be all that is noticed in mild bladder cases, but if severe there is much hæmorrhage, a heavy deposit of cells and débris, and often severe pains. A general septic cystitis may be superadded, and calculi and gravel are common. When the rectum is attacked, blood and mucus are passed in the fæces (Schistosomiasis or Bilharzial dysentery). The appendix may be specially involved, giving rise to Bilharzial appendicitis.

Diagnosis.—The ova are large objects and can be found in the urine or fæces with ease. The terminal spine indicates the presence of *S. hæmatobium*. This is the only certain method of distinguishing the condition from amœbic and other forms of dysentery. Eosinophilia in the blood is also suggestive.

Schistosoma mansoni (*Bilharzia mansoni*).—L. ♂ 12 mm. \times 0.4 mm. in the middle; ♀ 14–15 mm. \times 0.16 mm.; Ova, $146\mu \times 62\mu$. Oval, no operculum, sharp spine, placed laterally at one side of the egg. The intermediate host is a *Planorbis*, *Planorbis boissyi*.

Pathology.—This species is found in the rectal and mesenteric veins, and hardly ever lays its ova in the venules of the bladder. The lesions produced are similar to the rectal lesions of *S. hæmatobium*.

Symptoms.—Blood and mucus in the motions are the chief symptoms, a condition exactly resembling dysentery being again produced.

Diagnosis.—The lateral spine on the egg betrays the condition.

Schistosoma japonicum.—L. ♂ 8–12 mm. \times 0.5 mm.; ♀ 12 mm. \times 0.4 mm.; Ova, $70\text{--}75\mu \times 45\text{--}55\mu$. Oval, no sharp spine, but sometimes a little knob or nipple is seen laterally situated. The intermediate host is a snail, the *Hypsobia nosophora* (formerly *Blanfordia nosophora*). The anatomy of the worms is similar to the species just described; there are no tubercles on the male.

Pathology.—The lesions are somewhat different from those produced by the other bilharzia. The ova are deposited in the mucosa of both the small and large intestine and may be seen in very large numbers. They eventually ulcerate and escape into the fæces. The bowel wall becomes very greatly thickened by fibrotic changes. There is a peculiar form of cirrhosis in the liver, and the pancreas and mesenteric glands are also affected. The bladder escapes entirely.

Symptoms.—The entry of the cercariæ through the skin gives rise to some local irritation (Kabure disease). The symptoms produced later are known as *Katayama* disease. These depend upon the intensity of the infection. At first there is fever with an urticarial eruption, sometimes associated with pulmonary symptoms. A long interval then usually appears, after which intestinal troubles begin, with enlargement of the liver and spleen. Wasting is progressive, and anæmia and ascites develop. Finally a chronic cachexia sets in and the patient dies. The blood shows an eosinophilia. The stools are often dysenteric, with blood and mucus (*S. japonicum* dysentery).

Diagnosis.—This is made by finding the ova in the stools. Fever, with urticaria, and an eosinophilia should raise the suspicion of this condition.

Treatment of Schistosomiasis in general.—Antimony tartrate (tartar emetic) injections intravenously act in a specific manner on *S. hæmatobium* and *S. mansoni* infections. They are certain to act equally well on *S. japonicum* infection.

The injections are given in a similar manner as in kala-azar and trypanosomiasis (see treatment of these diseases, pp. 230, 235).

The first dose should be half a grain, and this should be increased by half a grain each dose on every second or third day, until $2\frac{1}{2}$ grains is reached. This quantity is then continued until 20–30 grains in all have been administered. The blood, as a rule, disappears from the urine and fæces after 6 or 8 grains have been given, and subsequently the ova. The clinical signs also clear up and the infection comes to an end. The drug evidently kills the adult worms so that no more ova are produced. Ova already laid and in the tissues are probably also destroyed. Local treatment should also be adopted for cystitis and bladder troubles if these be severe.

G. CARMICHAEL LOW.

II. DISEASES DUE TO CESTODES—TÆNIASIS

INTESTINAL TÆNIASIS—TAPE-WORMS

Definition.—An invasion with different forms of *Tænia* (tape-worms), either occurring as adult forms in the intestine (Intestinal tæniasis), or as the cystic stage in the muscles and other tissues of the body (Somatic tæniasis).

Diphyllbothrium latum.—L. 2–9 m. and over. Head almond-shaped, no armature. 3000–4200 segments. Ova, L. $68-71\mu \times 45\mu$. Oval, with an operculum. The segments are broader than they are long. The plerocercoid stage occurs in fish, the first stages being passed in a mollusc.

Symptoms.—This tape-worm lives in the intestine and its presence there gives rise to anæmia (toxic in origin), often of a severe grade. The mature segments are passed in the fæces.

Treatment.—As for other tape-worms.

Tænia solium.—L. 2–3 m. Head globular, four suckers, rostellum with double row of hooks. Ova, circular to oval, $31-60\mu$ in diameter. Uterus, 7–10 lateral processes. The cysticercus stage is reached in the pig (*Cysticercus cellulosæ*). Man acquires the parasite by eating badly-cooked infected pork.

Tænia saginata (*Tænia mediocanellata*).—L. 4–10 m. Head cubical, four suckers, but no armature. Ova, slightly oval-shaped, $33-40\mu \times 20-30\mu$. Uterus, 30–40 side processes. The cysticercus stage is found in the ox (*Cysticercus bovis*). Man is infected by eating badly-cooked infected beef.

Symptoms.—Gnawing pains in the stomach, attacks of colic, diarrhœa, loss of appetite, sometimes a voracious appetite with neurasthenia and mental symptoms are the chief symptoms.

Treatment.—The patient should be starved for two days, then on the morning of the third day extractum filicis liquidum in 30-minim doses is given as follows: one dose at 7, one at 7.15, one at 7.30 (90 minims in all), either in a capsule, or as an emulsion.

If a case have been treated before, with no bad symptoms, and the tape-worm recurs, an extra 30 minims may be given, e.g. 4 capsules of 30 minims, in all 120 minims, or 2 drms. This is the maximum dose. A purgative is taken at 10 a.m. This must not be castor oil as this dissolves the filicic acid. Sodium

or magnesium sulphate can be employed. The motions must be carefully examined to see if the head be passed or not. If not, segments will appear again in about 3 months' time. The writer has found it useful, when the head is not passed, to wait 10 days and then to repeat the treatment. This is often effective in obstinate cases. A capsule of 30 minims of oil of turpentine may be given with the last capsule of *felix-mas*.

Hymenolepis nana.—The dwarf tape-worm. L. 10–45 mm. Head: Scolex subglobular, rostellum with a single row of hooks. Proglottides, 100–200. Ova, oval or globular 30–60 μ in diameter. Common in Southern Europe and in parts of the tropics.

Symptoms.—Abdominal pain, attacks of diarrhoea. Convulsions in children and headaches and strabismus.

Treatment.—Male fern is efficient and may be given as for ordinary tape-worm. *Vide supra*. Thymol and ol. chenopodii are also effective.

SOMATIC TÆNIASIS—CYSTICERCUS STAGE

Tænia solium.—The cysticercus stage of *T. solium* is sometimes met with in man. The cysts occur in the connective tissues, in the brain, eye and other organs. Osler describes a case of generalised infection where the symptoms complained of were stiffness and weakness, with numbness and tingling in the extremities—an examination revealed a number of painful subcutaneous nodules, which proved on excision to be cysticerci.

Cysts may be present in the brain, in the silent areas, without giving rise to any symptoms, whereas in other areas localising signs are met with. When in the eye the condition can be more easily recognised.

The diagnosis is not as a rule easy. If the cysts be in the connective tissues and superficial, one may be removed for examination.

HYDATID DISEASE

Echinococcus granulosus.—L. 2.5–5 mm. Head, four suckers with a rostellum with hooks. Ova, globular, 30–36 μ across. The parasites live in the intestines of dogs, jackals and wolves. Man becomes infected in the cysticercus stage (hydatid cyst), by swallowing the eggs, which may contaminate his hands or sometimes his food. Intimate contact with dogs is seen in countries where the condition is common—Australia, New Zealand, Greenland, etc. The hydatid cysts in man may occur in the liver, brain, lung, peritoneum and other organs. Two forms are usually now described: *Echinococcus granulosus*, which forms the ordinary cysts, and *E. multilocularis*, the alveolar or multilocular type of lesion.

Development.—After the egg is swallowed the six-hooked embryo escapes from its shell and is carried by the circulation to the tissues or viscera. Here it loses its hooks and forms a cyst, this consisting of two layers—a laminated outer layer and a granular inner layer—with the tissues of the organ forming a fibrous capsule around. The inner or granular layer is also known as the germinal layer, and in time protuberances are seen upon it. These grow larger, push out into the cavity of the cyst, and form what are known as brood

capsules. The base of the brood capsule may gradually narrow till a pedicle is all that attaches it to the wall of the cyst, and then, if this breaks, it becomes free in the cyst—the brood capsules consist again of two layers, and on the inner one heads or scolices with minute hooklets appear. While this is going on a vesicle may form between the two layers of the wall of the mother cyst (secondary or daughter cyst), and by pressing on the inner layer gradually protrude into the cavity (endogenous daughter cyst); on the other hand, however, growth may take an outward direction, protrusion eventually taking place outside the wall of the mother cyst (exogenous daughter cyst). Both those varieties form brood capsules, and heads with hooklets (scolices) appear on their inner layers. A third generation may even follow, thus giving rise to what are known as granddaughter cysts.

The cysts often die and become caseous with calcification, or they may suppurate and form abscesses, or they may rupture. Growth is slow, and their length of life is not accurately known. The fluid in the cysts is colourless or slightly opalescent, with a specific gravity of 1005 or slightly higher, non-albuminous, but with traces of chlorides and sugar. Hooklets are present in the clear fluid and also in the pus in suppuration, the latter process killing the embryos. Occasionally the cysts are sterile, and in such cases hooklets will be absent.

Diagnosis.—When the cysts are of large size and within reach of palpation a peculiar thrill or fremitus—the hydatid thrill—may be elicited. Aspiration of some of the fluid may demonstrate the hooklets, or if those are not present, the absence of albumin and the presence of sugar will be helpful. Sero-diagnosis has recently been used, Weinberg and others employing the Bordet-Gengou fixation of complement method. A precipitin test has also been tried, and Bettencourt, by applying a hæmolytic system of human red cells and a rabbit homo-serum, has obtained positive results (Stiles). All these may fail, however, where suppuration has occurred in the cysts.

Treatment.—No medical treatment is of avail. Short of surgical procedures, simple aspiration of the cyst may be successful. In other cases the cyst requires to be opened and drained (See treatment of Hydatids in Liver, Lungs, etc.)

G. CARMICHAEL LOW.

III. DISEASES DUE TO NEMATODES

STRONGYLIASIS

Strongyloides intestinalis or *stercoralis* (*Rhabdonema intestinale*) is a common parasite of the intestines. Such parasites were at one time supposed to be concerned in some way with sprue, but this has not been confirmed. They may cause some intestinal catarrh if the infection be severe.

FILARIASIS

Definition.—An invasion of man with members of the family of the *Filaridæ*. Four species are known: *Filaria bancrofti*, *Filaria loa* (*Loa loa*), *Filaria perstans* (*Acanthocheilonema perstans*) and *Filaria demarquayi*. The first two only are of importance.

Filaria bancrofti.—L. ♂ 30-40 mm.; ♀ 76-100 mm. \times 0.2 mm. The adults are like fine catgut. They live in the lymphatic vessels and glands and breed there, the females giving birth to embryos, which find their way into, and live in, the blood stream. The embryos measure 0.310 mm. \times 7.5 μ , the breadth of a red-blood corpuscle, and are enclosed in a loose sheath. They live in the lungs and blood vessels of the thorax by day and only come into the peripheral blood at nights. The intermediate host is a mosquito (chiefly *Culex fatigans*) which sucks the embryos out of the blood at night. A metamorphosis takes place in the thoracic muscles of this insect, and when this is accomplished, the matured embryos are inoculated into man from the proboscis of the mosquito. They pass into the lymphatics and there develop into adults.

The parent worms may cause considerable damage to the lymphatic system, and give rise to a series of lymphatic diseases, filarial lymphangitis, abscesses, dilated inguinal glands, hydrocele, lymph scrotum, chyluria and elephantiasis.

Pathology.—The changes produced are due partly to mechanical obstruction of the parts, partly to toxins excreted by the adult worms. These produce changes in the endothelium of the vessels with inflammatory exudations and finally fibrotic changes which may completely obstruct both the glands and the vessels. As far as is known the embryos are non-pathogenic.

Symptoms.—These depend upon the nature of the lesion. Filarial lymphangitis is associated with high fever, enlargement of the lymphatic glands and inflammatory swelling of the part affected. After repeated attacks permanent thickening appears, and an elephantoid condition is the result. In chyluria the patient passes milky-white urine, often mixed with blood.

Treatment.—Prevention of mosquito bites is a *sine qua non*. Every one in the tropics should use a mosquito net. Towns and municipalities should enforce regulations for the destruction of all domestic mosquitoes. No drug has yet been discovered which will kill the adult worms. Antimony injections are being tried, but so far do not appear to be efficacious.

Loa loa.—The adults of this parasite inhabit the connective tissues, the embryos, the blood stream, occurring in the peripheral blood by day and not by night. The adults in their wanderings excrete toxins and these may cause the production of what are known as Calabar swellings. These are about the size of a small hen's egg, come up suddenly, with no redness or inflammation, and after lasting a day or two disappear. The adult worm may cross the conjunctiva and produce conjunctivitis and lachrymation.

Another member of the Filariidæ, the *Onchocerca volvulus*, is found in man in some parts of the West Coast of Africa. The parasite forms small tumours, cystic swellings, with a dense fibrous wall. Inside, the cyst is located, and contains the adult worms and numerous embryos. The cysts are superficial, over which the skin as a rule is movable. They vary in size from a pea to a pigeon's egg and are most commonly found on the lateral aspects of the thorax; along the iliac crests is another favourite site. The embryos are found in the cysts or free in the small lymphatic channels. A sandfly *Simulium damnosum* is the intermediate host.

A similar parasite the *Onchocerca cecutiens* is met with in Guatemala. It also gives rise to small nodes or tumours, often met with on the head, and

locally known as Guatemala nodules. A mosquito is supposed to be the intermediate host (Calderon).

Filaria medinensis (*Dracunculus medinensis*).—The guinea-worm. This worm inhabits the connective tissues, and the female, when mature, pushes her head to the surface, causing the skin to rise as a blister. This finally gives way, and out of the prolapsed uterus, the opening of which is close to the mouth of the parasite, the little embryos are ejected. These find their way into water and enter the tissues of a cyclops. Here they undergo development, and man is infected by swallowing the cyclops. The female guinea-worm is very long, 50–80 cm. \times 0.5 mm.–1.7 mm. It takes 12 months for the guinea-worm to come to maturity after the infected cyclops is taken into the body.

Pathology.—The worm causes irritation, very likely from the excretion of toxins, and if injured may abort her embryos into the tissues, causing an acute cellulitis, with abscess formation.

Symptoms.—As the parasite comes to the surface it causes a pricking sensation, with some local pain at the spot where it is about to point. The blister may not at first be recognised, but after it bursts a little orifice is noticeable in the centre of the raw surface. From this opening the embryos are ejected.

Treatment.—The affected part should be kept covered. Every day water should be dropped on the foot some distance away from the blister, and by doing this a daily discharge of embryos will be produced. After the uterus is emptied the end of the worm should be attached to a match and then gradually wound round it. It must not be pulled out, as otherwise it may break and set up severe inflammation. Cellulitis and abscesses are treated by ordinary surgical methods. Injections of tartar emetic have recently been reported as efficient.

TRICHINIASIS

Definition.—A condition or disease produced by the migration of the embryos of *Trichinella spiralis* from the intestinal canal of man to the muscles.

Ætiology.—Man becomes infected by eating flesh (pork) in which the embryonic stage of the worm is being passed. The cyst wall is dissolved by the gastric juice and the embryos develop into adult forms in the intestine, where they breed, the females giving birth to numerous embryos, which migrate into the lymphatics in the intestinal wall and are carried all over the body and deposited in the voluntary muscles.

The adults are small—♂ 1.4–1.6 mm. \times 0.04 mm.; ♀ 3–4 mm. \times 0.06 mm.

Symptoms.—Gastro-intestinal symptoms may usher in the disease, nausea, vomiting, diarrhoea and pains in the stomach. The most striking feature of the invasion period—which occurs 7 to 10 days after infection—is the myalgia, resulting from the inflammatory changes taking place in the muscles. The latter may be exquisitely tender, with severe pains on attempting any movements. Stiffness is often complained of, and the affected muscles are hard to the touch. In addition, fever of a remittent type, varying from 102° to 104° F., is common. Edema appears about the end of the first week, commencing on the face. Profuse sweating, urticaria and

erythematous patches have also been described. The blood shows a leucocytosis with a very marked eosinophil increase.

Diagnosis.—This may not be easy at first. The condition is often mistaken for rheumatism and typhoid. The increase of the eosinophils should put one on one's guard. A piece of muscle may be cut out and examined for the minute white specks which indicate the coiled-up embryos.

Prognosis.—This is uncertain. Convalescence is slow, and some muscular atrophy may follow.

Treatment.—Infected pork should not be eaten. Such meat should be condemned in the slaughter-house. The adults must be expelled from the intestine with all possible speed. Purgatives should be given and glycerine, santonin, turpentine and thymol are also employed.

ŒSOPHAGOSTOMIASIS

Definition.—A rare infection of man with members of the *Strongylidae* family.

Œsophagostomum brumpti and *O. stephanostomum*.—The worms form small cysts in the walls of the small and large intestine, oval in shape and 2–3 cm. in length. Both the inside and the outside of the bowel are implicated. When a cyst is opened, a small worm is seen occupying its interior. The mesenteric and retro-peritoneal glands are enlarged.

Symptoms.—In Thomas' case in Manaos the patient was admitted into hospital for severe dysentery, with delirium. The true nature of the infection was diagnosed after death.

Treatment.—None is known.

ANKYLOSTOMIASIS

Definition.—An invasion of the human subject with members of the family of the *Ancylostomidae*. Three species are known to affect man: the *Ancylostoma duodenale*, the *Necator americanus* and the *A. ceylanicum* (rare).

A. duodenale.—L. ♂ 8–10 mm. \times 0.4–0.5 mm.; ♀ 12–18 mm. \times 1 mm.; Ova, elliptical, thin-shelled, vitellus generally segmented into 2 or 3 spherules, 55–65 μ \times 32–45 μ .

Necator americanus.—L. ♂ 7–9 mm. \times 0.3 mm.; ♀ 9–12 mm. \times 0.4 mm.; Ova, 64–75 μ \times 36–40 μ . Larger than the preceding species.

The buccal armature of the two species differs. The buccal capsule is smaller in *N. americanus* and has an irregular border instead of the 4 ventral hook-like teeth of *A. duodenale*. There is also a ventral pair of semilunar plates. The pathology, symptoms and treatment apply equally to both.

Pathology.—The life history of the worms is as follows. The ova escape in the fæces, and if passed into suitable surroundings embryos emerge. After moulting, such embryos bore their way through the skin of man, pass to the lungs, then into the trachea, and subsequently down the œsophagus into the duodenum and small intestine, where they become mature and breed. The worms attach themselves by their buccal apparatus to the mucosa and feed on it. By their constant bites they produce small hæmorrhages; they

also excrete a toxin. On autopsy extreme pallor may be noted; œdema over the legs and sacrum is common. Fluid is generally present in the serous cavities and petechial hæmorrhages on the pericardium and pleural surfaces. The heart is often hypertrophied, especially the left ventricle; the myocardium is soft, pale, friable and of a yellow colour like a thrush's breast (fatty degeneration). The liver in the early stages is the colour of a nutmeg, in the later almost completely yellow and very friable. The spleen is normal, the kidneys fatty. The duodenum and upper part of the ileum show small petechial spots where the worms have been attached, with occasionally large hæmorrhages in the submucous coat. Microscopically the tissues exhibit the usual changes of fatty degeneration.

Symptoms.—These vary considerably with the extent of the infection, which falls principally on the alimentary and circulatory systems. The patient tires easily, appetite is impaired and there may be a desire to eat abnormal substances. In addition there is pain in the epigastrium and often nausea and vomiting. There may be diarrhœa and blood in the stools (Ankylostomiasis dysentery). The usual subjective signs of a severe anæmia are present; dyspnœa on exertion, palpitation, præcordial pain, etc. On auscultation hæmic murmurs are to be heard.

The blood shows anæmia of a secondary type, which according to some may pass into pernicious anæmia. Sometimes the hæmoglobin follows the chlorotic type, though in many cases the colour index is somewhere about 1. Eosinophilia (18–20 per cent. on an average) is present. A dermatitis is seen at the site of entry of the embryos (coolie itch, Ankylostomiasis dermatitis).

Diagnosis.—Anæmia with eosinophilia in a person who has lived in the tropics is suspicious. The stools should then be examined and the presence of the characteristic eggs will settle the diagnosis.

People should not walk bare-footed on fæcally contaminated soil. Ground known to be contaminated should be dug up, if possible, and lime strewn thickly on it. Infected coolies should be treated and promiscuous defæcation forbidden, latrines being always used.

Treatment.—There are five main drug treatments in use, namely, thymol, β -naphthol, oleum chenopodii, carbon tetrachloride, and the eucalyptus castor-oil mixture. After a preliminary starvation of two days, with purgation, 30 grains of thymol or β -thymol are given in a cachet, at 6 a.m., 8 a.m. and 10 a.m., followed by a saline purge at 12 noon; or instead oleum chenopodii, ℥viii (0.5 c.c.), may be administered at 6 a.m., 8 a.m. and 10 a.m., followed by a purgative at 12 noon. This method sometimes succeeds where thymol fails. It is efficacious in ascariis and strongyloides infections also. Carbon tetrachloride is given to adults in doses of 3 c.c., 50 minims approximately, and the preliminary starvation has not to be so drastic. It sometimes causes sickness and nausea.

The eucalyptus mixture consists of ol. eucalypti, ℥xxx; chloroform, ℥xlv; ol. ricini, 3x. This is divided into two portions, one being given, say, at 9 a.m., the other at 9.30. No purgative is required, the castor oil being sufficient.

All these methods may be followed by poisoning symptoms. No alcohol, ether, glycerine, turpentine, chloroform, fats or oils must be given with the thymol or β -naphthol, as they act as solvents of the drugs, rendering absorption possible. Carbon tetrachloride is said to have caused fatty degeneration

of the liver, similar to delayed chloroform poisoning. ~~The aim with all anthelmintics is to pass large doses of the drug through the intestines quickly without absorption.~~

After the purgative, the number of worms passed is counted. The stools are then checked for a week or ten days, and if ova reappear, a complete cure has not been obtained. In that case, another course of treatment will be required. If thymol has been given the first time, it may be repeated, or one of the other methods may be employed in its place. Quassia, filix mas, oil of peppermint, kerosene, carbonate of guaiacol, and areca nut have also been used. The dosage given above is for adults, appropriate reductions being made for children.

ASCARIDIASIS

Definition.—The presence of round worms (*Ascaris lumbricoides*) in the intestine. L. ♂ 17–25 cm. × 3 mm.; ♀ 20–40 cm. × 5 mm.; Ova, 50–70 μ × 40–50 μ . Elliptical with thick outer shell. Yellow colour. The ova escape in the faeces. These are swallowed by man in due course, and if they contain mature embryos, the latter pass from the intestines, as Stewart has shown, to the lungs, where they undergo development, then into the trachea, and so back into the intestine, where they become sexually mature adults.

Symptoms.—The presence of ascarides in the intestines may give rise to many symptoms. In children convulsions are common; gnashing the teeth, abdominal pains and intestinal obstruction from a knot of coiled-up worms may occur. The worms have a tendency to wander and may pass up and obstruct the bile-duct, causing jaundice, or into the liver and produce liver abscess. They have even been known to enter the larynx and give rise to suffocation. Intestinal symptoms are also common, purging, with sometimes blood in the motions (*Ascaris dysentery*). Oedema of the face, hands and feet, simulating Bright's disease, has been reported, and also curious skin rashes. Appendicitis may be set up if a worm enters the appendix. Symptoms of broncho-pneumonia, due to the passage of the embryos through the lungs, are common in children.

Treatment.—Santonin is the stock remedy. It should be given, after the usual starvation, three times on alternate days, in doses of 5 grains for an adult, with smaller doses in proportion for children. For the latter it may be combined with scammony; or it may be administered as an emulsion with castor-oil. The worms may take a day or two to be ejected. The proof that all have been removed lies in the absence of ova on subsequent examinations.

TRICHURIASIS

Definition.—The presence of *Trichuris trichiura* (*Trichocephalus dispar*) in the cæcum. The trichocephalus or whip-worm chiefly inhabits the cæcum. Whether or not it produces pathological symptoms is not certain. Very severe infections might quite likely cause some intestinal disturbance. It has been known to enter the appendix and excite an appendicitis. L. ♂ 40–45 mm.; ♀ 45–50 mm.; Ova, 50–54 μ × 23 μ . Brown colour, barrel-shaped, with a little knob at each end. Posterior part of body thick, rolled up in male, anterior part drawn out into a whip-like process.

Symptoms.—The infection is a very common one in the tropics, almost all natives harbouring the parasites.

Treatment.—Thymol and chenopodium may be tried and are said sometimes to be efficient, but the worms are difficult to remove.

ENTEROBIASIS

Definition.—Infection by the thread or pin worm, *Enterobius vermicularis*.—L. ♂ 3–5 mm.; ♀ 10 mm. \times 0.6 mm.; Ova, $50 \mu \times 20 \mu$. Thin-shelled, a developed embryo often being noted inside the adult.

Symptoms.—Irritability of the bladder with frequency of micturition, tenesmus, prolapsus ani and a secretion of mucus may all be observed. In girls a vaginal discharge is common. The worms live in the colon and by descending and passing out of the anus at night cause great discomfort, itching and pruritus. A strong tendency to neurasthenia develops in adults. Itching at the anus is, however, the chief complaint, often rendering sleep at night impossible.

Treatment.—Infected children should occupy separate beds; the hands should be kept clean and the nails short.

Santonin may be tried, but it is not so good as in ascaris infections. Naphthalene sometimes does good—10 grains and upwards, 3 grains for a child.

Most success is, however, obtained by local methods. The rectum is first cleaned out by a warm-water enema, and then an injection of 6 to 8 oz. of a solution of the drug to be employed is given. Salt water, inf. quassia, tinct. of iron 40 minims to the pint; creosote, $\frac{1}{2}$ per cent. solution; sulphate of copper (1–2000) or thymol (1–2500) are all recommended.

For the local anal discomfort orthoform as an ointment, or one or other of the mercurial ointments, such as ung. hydrarg. or ung. hydrarg. nit. diluted, will be found useful.

G. CARMICHAEL LOW.

IV. DISEASES DUE TO INSECTS

MYIASIS

Definition.—An invasion of the tissues by larvæ of dipterous insects.

Ætiology.—Several flies deposit their eggs upon man, the larvæ developing in the nasal cavities, under the skin or in the intestinal canal. Two varieties are thus distinguishable, the dermal and the intestinal.

DERMAL

The screw worm (Chrysomya macellaria).—This fly, common in the West Indies and adjacent areas, is like an ordinary blue-bottle, from which, however, it can be distinguished by the presence of 3 linear marks on the dorsum of its thorax. It measures 9 to 10 mm. in length. It has a habit of laying its eggs upon foul wounds, and from these larvæ hatch out in a few hours. They

resemble a screw superficially, and are formed of 12 segments, each with a series of spines. Whenever hatched they burrow quickly into the tissues, upon which they feed, causing great destruction of the parts invaded. When the nose is affected, the larvæ pass up into the accessory sinuses, bore their way through the bones, and even penetrate the skull, causing death by purulent meningitis. The vagina or ear may be attacked as well as any ulcers or wounds on different parts of the body.

Treatment.—Avoid sleeping in the open. Great care must also be taken to protect all wounds, and people with nasal or aural discharges must take special precautions to protect these orifices from the attacks of such flies. They are specially attracted by foul-smelling discharges of all sorts. They can be removed from wounds by ordinary antiseptic methods. For nasal cases, injections of chloroform, carbolic acid and turpentine are used. The accessory sinuses may have to be opened.

The mosquito worm—

Synonyms.—Ver macaque. Beef Worm.

This is the larvæ of a fly, the *Dermatobia hominis* vel *cyaniventris*, common in Central America, northern parts of South America, Trinidad, etc. It measures 14 to 16 mm. in length, has a yellow head, with brown eyes, with a greyish thorax, and dark metallic blue abdomen. The eggs are deposited in damp ground, where a mosquito, the *Janthinosoma lutzii*, frequents. In some way or other the eggs get attached to the mosquito's thorax and are conveyed by it to the skin of man, where the larva comes out of the egg, drops on the skin and finds its way through the hole made by the puncture of the mosquito. Here it develops, and in doing so produces a boil or warble of a very painful nature. This enlarges as the larva grows, and if carefully observed will be seen to have a minute opening at the top, out of which a black material exudes—the fæces of the maggot. Finally the parasite escapes through the opening, falls on the ground and becomes a chrysalis. In due course the fly emerges. Cattle are often affected with multiple warbles all over their backs, whence the name beef-worm.

Treatment.—The natives kill the larva with tobacco juice and then squeeze it out. The opening should be enlarged with a bistoury, and the maggot removed with a pair of forceps. The cavity soon heals up if treated antiseptically.

Ver du Cayor—

Synonym.—Tumbu Disease.

This is the larva of an African fly known by the name of the *Cordylobia* (*Ochromyia*) *anthropophaga*. The infection is common in various parts of the West Coast, and other parts of Africa. The fly measures from 8.5 to 11.5 mm. in length, and is of a yellowish colour with black abdominal spots. The eggs are laid on clothing or on the skin, the larva on emerging boring its way into the tissues by means of its mouth hooks. The first sign of its presence is a pricking sensation, and then the boil or warble develops, often with considerable inflammation around it. A central hole allows of the ejection of the fæces, and ultimately of the larva itself when mature. The cavity may suppurate.

Treatment.—Squeeze the maggot out, enlarging the aperture if necessary, and then treat the cavity antiseptically.

The Congo floor maggot.—At one time it was supposed the larvæ of the

Auchmeromya luteola (*Musca luteola*) occurred under the skin of natives, but these were probably the larvæ of some other fly, as more recent work has shown the maggots live in the dust of the floors of houses and outhouses, emerge at night and suck the blood of any one sleeping on the ground. They can crawl about quite actively, and consist of 11 segments, measuring when full grown 15 mm. in length. The fly is an orange-yellow colour with two longitudinal stripes on the dorsum of the thorax, and measures 10 to 12 mm. in length.

INTESTINAL

Larvæ of flies are common in human fæces, some of these having come from the intestinal tract. Something like 20 different species have been described, the genera *Sarcophaga*, *Fannia* and *Apiocæta* furnishing most examples. The eggs are taken in with food, dirt, vegetables, etc. There may be gastro-intestinal symptoms as a result, diarrhœa and griping; general symptoms such as headache, thirst, rigors, vertigo and convulsions have also been described.

Treatment.—Castor oil should be used to clear out the bowel thoroughly. Thymol, filix-mas and santonin have also been tried. Soltau Fenwick recommends turpentine.

TUNGIASIS

Synonyms.—Chigger Disease; Chiggers; Jiggers; Sand Flea Infestation.

Definition.—An infestation of the skin with the burrowing flea or chigger.

Ætiology.—The disease is endemic in South America, and has spread to Africa, and now even to India. All races are affected, and both sexes. Children often suffer severely. The flea, the *Tunga penetrans*, lives in the dust or mud of earth floors, and the impregnated females burrow in under the skin, where they come to rest, and gradually swell as their eggs develop. When the ova are mature they are expelled and fall on to the ground where the larva hatches out, this in turn becoming a chrysalis, from which in 14 days or so the adult flea emerges.

Pathology.—The chigger acts as an irritant as it grows, causing inflammation and often suppuration of the sac in which it lies. When mature, the swellings are the size of a fair-sized pea, and appear as little inflamed nodules; in some instances the skin is raised in the form of a blister. Finally ulceration takes place.

Symptoms.—The first thing noticed is a slight smarting or pricking sensation where the chigger is located; if on a toe it feels as if the boot were irritating the part. Later on, definite pain occurs with, as the inflammation spreads, itching and redness. As a rule the nature of the trouble is then suspected, and the parasite removed, when all the symptoms quickly clear up. Tetanus has been noted as a result of the tetanus bacillus gaining access from the ground into the sores. Sometimes the parasite is located under the nail and gives rise to a very painful onychia.

Diagnosis.—This is easy, and may often be made before the swelling has reached any size. People in chigger areas periodically inspect their toes

and if any little brown mark be seen it is picked out with a sharp-pointed needle.

Prognosis.—This is quite favourable, unless there is a very large infection. The ulceration is often extensive, and the patient lamed and rendered unable to walk for long periods of time.

Treatment.—Tobacco infusion to the floors and areas where the chiggers are, at the same time soaking one's boots and shoes in a little of the mixture, is the best preventive. Removal of the chigger as soon as possible, and cleansing the sore with a little carbolic lotion is all that is required.

BÊTE ROUGE

Synonyms.—The Red Mite, *Tlalsahuate*, Balata, Pou d'Agoute.

Definition.—Infections of the skin with the red mite, *Trombicula thalzhual*.

Ætiology.—The disease is similar to the papular eruptions produced by the ordinary harvest bug in England.

Symptoms.—After penetrating the skin the mites set up an itchy, papular eruption known by the name of Red Mite dermatitis.

Diagnosis.—This is easy, the little crimson spot in the middle of the papule supplying the clue.

Treatment.—The spots may be touched with pure carbolic or sulphur ointment, or tincture of iodine may be employed.

V. DISEASES DUE TO SNAKES

OPHIDIASIS

Synonyms.—Snake Poisoning.

Definition.—Poisoning, often of a deadly and fatal nature, produced by the bites of different snakes.

Ætiology.—The tropics are the chief home of most of the deadly snakes; in England there is only one poisonous variety, the viper. All races are liable to attack, children and adults alike, and both sexes equally.

There are many varieties of snakes, the cobra, *Naja tripudians*, the coral snakes, the vipers, the rattlesnakes, etc. The poisons of the different examples differ in their action on the human organism, some being of the nature of neurotoxins, others of the nature of agglutinins and still others of the nature of cytolytins, the latter group including the hæmolysins, the hæmorrhagins and the leucolysins. Colubrine neurotoxin is said to act upon the respiratory centre in the medulla, while viperine neurotoxin acts upon the vasomotor centre. Colubrine venom (cobra, for example) causes paralysis of movement, salivation, paralysis of respiration, lachrymation and mucous discharges from the nose, etc. Viperine venom (*Vipera russelli*) causes intravascular clotting of the blood, while that of *Echis carinatus*, a viperine snake common in dry tracts of South-west Asia and Tropical Africa, acts as a coagulant in the first instance, but when absorbed causes hæmorrhages, evidenced by hæmaturia, etc.

Symptoms.—The symptoms will depend upon what sort of poisonous snake has bitten the patient, and also as to what amount of poison has been introduced.

Diagnosis.—This depends upon whether the snake is a poisonous one or not, and also whether the patient really is bitten or not. It is important then to look for fang marks and any signs of venom on the skin.

Prognosis.—If a person receive the full dose of any of the poisonous varieties, death is certain, unless, perhaps, some of the antivenene of the species that inflicted the bite is immediately available. Many cases supposed to have been bitten by poisonous varieties have probably only been bitten by harmless ones. The prognosis also depends upon the amount of venom injected.

Treatment.—The first aim of treatment is to try to prevent the venom reaching the general circulation. A ligature must be tied round the affected finger or limb, and then the area of the bite should be freely incised and potassium permanganate crystals, dissolved to form a strong solution, rubbed freely into the wound.

If the patient recovers, the after treatment of the wound consists in keeping the parts clean, and if sloughing occur, treating the part with ordinary antiseptics. Once the poison has entered the general circulation, an attempt should be made to neutralise it, and this is done with antivenene. This must, however, have been prepared from the same species of snake that has inflicted the bite, otherwise it is useless, *e.g.*, viperine antivenene will not protect a person bitten by a cobra. The antivenene should be introduced intravenously. General symptoms must also be combated, failure of respiration by artificial respiration, heart failure by cardiac stimulants, alcohol, ammonia and strychnine. A binder should be applied to the abdomen, and bandages to the limbs.

POROCEPHALIASIS

Definition.—An invasion of the tissues by the larval forms of different species of *Porocephalus*.

Ætiology.—The adult forms of the parasite, *Porocephalus armillatus* and *P. moniliformis*, inhabit the lungs of snakes, while the larval stages are usually met with in monkeys, lions and hedgehogs. Accidentally, the eggs may be ingested by man, and then the larvæ encyst in the different viscera, such as the liver, lungs, peritoneum, etc. Zoologically, these creatures belong to the Arachnoidea, the body being annulated, and often being mistaken for a worm. The females measure 10 to 12 cm. in length by 6 to 9 mm. in breadth, and possess a mouth surrounded by a chitinous ring with two protractile hooklets on either side of it. The nymphal forms, which are found encysted in the tissues, are usually coiled up spirally, and resemble the adults in miniature. These develop from ova passed by the adults, when taken up by the intermediate host in water or food. When a snake swallows an infected monkey, for example, the cyst wall is dissolved and the young forms are liberated, finding their way to the lungs, where they develop into adults.

Pathology.—A heavy infection of cysts might give rise to various

troubles, whereas one or two are probably of little importance. Occasionally, the larval forms emerge from the cysts and wander about the peritoneum and in such a case are dangerous. Most of the reported cases in man have been met with accidentally at autopsy.

Treatment.—None is known.

Prophylaxis.—Avoidance of food likely to be contaminated, and care in drinking water that has not been boiled, is all that can be done.

G. CARMICHAEL LOW.

SECTION V

DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

CAISSON DISEASE

Synonyms.—Compressed Air Illness ; Diver's Paralysis.

Definition.—Caisson disease is the name given to a series of phenomena which may result in any living animal upon return to a normal atmospheric pressure after exposure to an air pressure which must exceed 18 lb. to the square inch above mean atmospheric pressure. These phenomena occur the more frequently and severely the greater the air pressure, and in direct proportion to the length of time of exposure to the high air pressure, and the more rapid the return to a normal atmospheric pressure. They are caused by the saturation of the living tissues with nitrogen at high atmospheric pressure which, on too rapid return to lower atmospheric pressures, boils within the tissues, and this liberation of bubbles of nitrogen causes tissue disruption and destruction on the one hand, and gas emboli on the other. The major capacity for fat to hold nitrogen in solution causes the liberation of nitrogen bubbles to occur most readily in the fatty tissues, and this occurs more easily in those parts of the body where the blood supply is less abundant, and therefore the rapid return of the excess of nitrogen to the atmosphere by solution in the blood stream, less easy. For these reasons the white matter of the nervous system, composed as it is of fatty substance, and particularly those parts of it which are less liberally supplied with blood, such as the white matter of the lower dorsal spinal cord, is the most common site of gas liberation. The joints and also their surrounding structures, which are lowly vascularised, are also common sites of the lesions, as are also the subcutaneous tissues of fat subjects, on account of the high solubility of nitrogen in the fat.

These phenomena occur only upon decompression, and are always preventable if adequate means be adopted (1) to limit the time of exposure to very high atmospheric pressures, so that high degrees of tissue saturation with nitrogen shall not occur, and (2) to regulate the return to normal atmospheric pressure by graduated decompression, in such a way as to prevent boiling of nitrogen in the tissues. They are curable, after they have appeared, by immediate recompression followed by very gradual decompression. Exposure of the living animal to very high atmospheric pressures may be associated with most serious and usually fatal results, which occur before decompression, and which are due to over-saturation of the tissues with oxygen, death resulting from oxygen poisoning.

Ætiology.—This disease made its appearance in the middle of the nine-

teenth century, when the invention of Siebe's diving dress and of subaqueous chambers made it possible for subaquatic engineering and marine salvage to be performed under high atmospheric pressures. The men work in a pressure of air, which just exceeds the hydrostatic pressure of that depth of water which extends from the working position to the surface, and the pressure is produced and maintained by pumps and regulating apparatus. Workmen reach the working face of the caisson by passing from the normal atmosphere through a series of chambers with airtight doors, in which the air pressure is raised by rapid stages, until the high pressure of the working face is reached. They leave through the same chambers, the air pressure being lowered for some space of time in each as they pass through. This process is termed "compression" and "decompression," or "locking in and out." The diver is compressed as he slowly descends by an increasing air pressure from his pump, and is decompressed as he ascends much more slowly, this compression being regulated by an automatic valve in his helmet which retains the air pressure until it exceeds that of the water pressure outside. Caissons are worked under a much lower pressure than that at which divers can work; but the working shifts are much longer, whereas the diver at great depths remains down only a very short time. Roughly speaking, each 33 feet of water produces a pressure of 15 lb. to the square inch ($5\frac{1}{2}$ fathoms). Caissons are usually worked at a pressure of below 35 lb. and in 6- to 8-hourly shifts, but they have been successfully worked at a pressure of 45 lb. with 2-hourly shifts, and at 50 lb. with 1-hourly shifts. Divers frequently work at 20 fathoms (53 lb.), and the record depth and pressure reached has been 210 feet (95 lb.).

During compression no trouble is experienced beyond discomfort in the ears and rarely perforation of the membrana tympani, from disparity of air pressure in the middle ear. This the workmen avoid by opening the Eustachian tubes with an act of swallowing or yawning; but it must be remembered that no person suffering from Eustachian catarrh should be allowed to enter the air locks. Under high atmospheric pressures combustion proceeds more readily, a candle when lighted burns away furiously, and a pipe bursts into flame with each draw. The workmen find that they can work more easily and with less fatigue.

The symptoms of the disease become manifest upon return to a lower atmospheric pressure, and directly in proportion to the suddenness of return to such pressure. If the return to a normal atmospheric pressure from a high and prolonged pressure be sudden, there may be a liberal escape of bubbles of nitrogen gas in the blood and in the tissues. The presence of the nitrogen may sometimes be felt as gas crackling underneath the skin or subcutaneous emphysema.

When the return to a normal atmospheric pressure is more gradual, the nitrogen may have time to escape from the blood and from most of the tissues by diffusion through the lungs, but in those tissues which are relatively less vascular, and from which, for that reason, interchange of gases by means of the blood stream is slow, or in those tissues in which nitrogen is especially soluble, such as the fats and myelin of the nervous system, the nitrogen is liable to escape in the form of bubbles, and to the mechanical effects upon the tissues in which the boiling of the nitrogen occurs, the symptoms of caisson disease are due.

350 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

That part of the nervous system which is least vascular, namely the four lower dorsal segments of the spinal cord, is the most common region for the lesions to occur, while the joints and peripheral nerve trunks are often affected.

Massive escape of gas may occur into the blood stream, and the heart has been found distended with gas after death in rapidly fatal cases. A similar escape of gas into the intestines may produce severe and even fatal abdominal distension. It is doubtless one of the causes of the abdominal pain, nausea and vomiting which are common symptoms of compressed air sickness.

The liberation of these gases, and therefore the occurrence of the compressed air disease, depends directly upon these factors—(1) the amount of pressure to which the living animal is exposed; (2) the length of time of exposure to the high pressure; and (3) the rapidity with which a return is made from the high pressure to normal atmospheric pressure. For example, the malady never occurs after short exposures, such as 15 minutes at a pressure of 45 lb., or 2 minutes at a pressure of 75 lb., even though decompression be as rapid as possible, for these periods are too short to allow of nitrogen saturation of the tissues. It is for this reason that compressed air sickness is so much less common in divers, who for the most part work for very short times only at high pressures, and so much more common in caisson workers, who work for many hours at a stretch at a pressure of from 30 to 40 lb.

There is one other factor which must be carefully borne in mind, and that is the amount of fat present in the body, which, from its nitrogen dissolving qualities, greatly increases the tendency to nitrogen boiling within the tissues if it be present in large amount. It has been shown experimentally that fat animals succumb to the disease while lean ones escape, and experience has shown the necessity of excluding fat workmen on account of their liability to the malady.

The disease is obviously always preventable, firstly by shortening the periods of exposure according to the height of the pressure so as to obviate nitrogen saturation; and secondly by arranging that such a graduated and prolonged return to normal pressure be made, as will prevent any possibility of nitrogen boiling, the slow return to normal pressure allowing of the nitrogen desaturation of the tissues without bubble formation.

It is quite safe, and does not produce any ill effects whatever for a man to breathe pure oxygen for as many as 6 hours at a time. This has been proved by the use of the Siebe-Gorman life-saving dress for rescue work from choke damp in mines. Beyond a certain limit of pressure, however, oxygen becomes poisonous. Highly compressed air causes rapid toxic effects in proportion to the partial pressure of the oxygen. It tends to cause direct death of the tissues. At lower partial pressures it has a convulsant effect, and at still lower pressures produces congestion of the tissues and especially of the lungs, which may present consolidation and all the signs of acute pneumonia, however slowly and carefully decompression has been accomplished. The limit of safety so far as oxygen poisoning is concerned is 10 atmospheres, or 300 feet of water. Neither divers nor caisson workers ever work at anything like so high a pressure.

The essential feature on post-mortem examination is the presence of bubbles of nitrogen in the tissues or bulky collections of nitrogen within the

organs, as in the heart or in the intestines, and the results of the associated tissue disruption and air emboli. When it is considered that the mass of blood constitutes about 5 per cent. of that of the whole body, and that the capacity of the tissues in a thin subject is thirty-five times that of the blood, the ratio being much higher in a fat subject since fat will dissolve five times as much nitrogen as will any other tissue, the presence of bubbles in the tissues, and especially in the fatty tissues, will readily be understood.

The bubbles form first in the venous blood and in the fatty tissues, where they grow by accretion and cause tearing of the tissues, while air emboli and subsequent necrosis are common. Hundreds of bubbles have been counted in the spinal cord, and these are much more numerous in the white than in the grey matter. Collections of nitrogen may be found in the subcutaneous tissues, and may cause palpable crackling. Bubbles of gas are not uncommonly found in the liver cells. Occasionally similar lesions are found in the brain or in the eye, and in fact may occur in any of the tissues. In every fatal case which has been adequately examined ~~patches of~~ necrosis in the dorsal region of the spinal cord, with the usual secondary degenerations, have been found.

Symptoms.—The symptoms may be first manifest during the process of decompression, when the latter is rapid, and from a high pressure. More often the signs of the malady appear soon after a normal pressure is reached, while not infrequently they do not present themselves until an hour or more has elapsed. In slight cases headache, giddiness, diplopia and faintness may occur, and these symptoms pass off soon and leave no trouble. Severe and important symptoms occur in the following order of frequency: (1) pain in the extremities or trunk, commonly called by the workmen "the bends" from the position in which the painful limbs are held; (2) pain in the epigastrium, sometimes accompanied by nausea, vomiting and abdominal distension; (3) paraplegic paralysis which usually involves motor, sensory and sphincter functions, and extends as high as the ninth dorsal segmental level; (4) headache, vertigo and coma; (5) sudden death; (6) hemiplegia or monoplegia of cerebral origin.

The pain in the limbs is of a neuralgic character and is referred to the joints, which are kept in the semiflexed position, any attempt to straighten them causing great pain. The pain may come on gradually, or suddenly, and may be slight and transient, or severe and persistent. It is often intolerable. The knees, ankles and hips are the most frequently affected; but sometimes the joints of the upper extremities, or of the back and especially of the lumbar region, may be affected. Epigastric pain is common, and unless quickly relieved by recompression is followed by nausea and vomiting.

The paraplegia usually has its upper limit in the lower dorsal, but it may reach the cervical region and involve the arms. It comes on rapidly, and involves motor, sensory and sphincter functions. It may be of any degree of severity from a slight and transient effect to a complete and permanent loss of the functions of the spinal cord. The paraplegia occurs with increasing frequency and completeness in proportion to the degree of pressure and the length of exposure to its influence. It occurred in 61 per cent. of 119 cases in the St. Louis bridge caissons, which were worked at plus 50 lb. of pressure, and among these there were 14 deaths. There is no general relation between the pain and the paralysis, as either may occur

without the other, and it seems, therefore, that the pain is due to a peripheral lesion and not to the lesions of the spinal cord. It is an interesting fact that the peripheral pains may persist in severe degree, even when there is total loss of pain sensibility from the spinal cord lesions.

Course and Prognosis.—The duration of the attack may vary within very wide limits. The severity of the initial symptoms, and the immediate application of appropriate treatment, are the all-important modifying factors in the prognosis. The attack may last for a few hours only, or it may continue for days. The paralysis may recover in a few days, or it may last for months and may never recover. Death occurs only in cases which have severe initial symptoms, and except when occasioned by complications such as cystitis and bed-sores it usually takes place shortly after the attack.

Treatment.—*Prophylactic.*—Since the malady is due entirely to nitrogen saturation of the tissues, and the subsequent escape from solution of this gas into the tissues during a too rapid return to normal pressures, it follows that the malady can always be prevented by adopting suitable period lengths for compression. In the first place, the malady never arises from compressions below plus 18 lb. to the square inch, or roughly 40 feet of water, and those who work at such a pressure may do so for long hours and return to a normal pressure rapidly, and without any risk. At higher pressures the working shifts must be shortened as the pressure gets higher. The shifts should be not longer than 6 to 8 hours at a pressure of 30 to 35 lb., or 3 atmospheres; 2 to 3 hours at a pressure of 45 lb., and 1 hour only at a pressure of 50 lb. At higher pressures than this, which are only encountered by divers, a few minutes' exposure is allowed only.

Compressed air sickness never occurs if the return to the normal atmospheric pressure be sufficiently slow. Animals can be exposed to very high pressures short of those causing oxygen poisoning, with impunity, provided they be decompressed slowly enough. This decompression is carried out in the case of the diver by raising him to various levels in stages, and letting him remain at each stage a longer and a longer period as the surface is approached. In the case of caisson workers a series of air-locked chambers is provided in which the air pressure is lowered in stages, the men remaining longer and longer at each stage as they approach the normal pressure. The important fact in connection with decompression is that the absolute pressure can always be halved forthwith without any risk. In the first air lock on leaving the working face of a caisson, for example, the pressure is at once reduced to one-half that of the working face, and in the remaining air locks the pressure is reduced by stages until zero is reached.

Leonard Hill has shown experimentally that it is always safe to lower the pressure to plus 20 lb. by gradual decompression during the space of 10 minutes, then to wait at that pressure for 2 hours, and then bring the pressure to zero by gradual reduction in 10 minutes. The Admiralty rules for divers require that a diver working, say at 140 feet shall be first raised straightaway to a depth of 50 feet where he waits 10 minutes, then to 40 feet for 10 minutes, 30 feet for 20 minutes, 20 feet for 30 minutes, 10 feet for 35 minutes, and then he leaves the water abruptly.

The difficulty and danger is the tendency on the part of the workers to curtail these weary waits, and get away from work as soon as possible. It is important that all fat subjects, and all those who have shown a

susceptibility to compressed air sickness, and all those not in absolutely sound bodily health, shall be excluded from working in highly compressed air.

Curative.—It was early discovered by the caisson workers themselves that the only remedy for the malady was to re-enter the high-air pressure. A recompressing apparatus in the form of a medical air lock is now supplied at all caisson works, and on all ships engaged in deep salvage. On the appearance of any symptoms the worker is placed in the compressing room and the pressure is run up to the full pressure at which he has been working, when it is usual for the symptoms to ameliorate rapidly or disappear. After the recompression the decompression must be carried out very slowly, for the bubbles once formed in the tissues are not easy to get rid of, though they may be kept at a small size by the pressure. Cases apparently at the point of death with cyanosis and coma have many times been completely recovered in a few hours by recompression. When symptoms have appeared, the decompression should take at least 5 hours. Caisson workers and divers should sleep and live close to the medical air lock that they may be near aid during the first hours following decompression. The paralysis when once established is to be treated upon ordinary lines.

ANOXÆMIA

Synonyms.—Altitude Sickness ; Mountain Sickness.

Definition.—A series of phenomena which occur in the human subject when breathing an atmosphere in which the partial pressure of oxygen is greatly reduced and which are entirely due to deficient oxygenation of the tissues. They are met with from the respiration of the rarefied atmosphere at high altitudes in mountain climbing and aviation, and are increasingly prone to occur with altitudes above 14,000 feet. They can be produced experimentally by breathing an atmosphere rarefied within a closed chamber and by dilution of the ordinary atmosphere with nitrogen, and can be avoided even in a highly rarefied atmosphere by continuous oxygen inhalation.

Pathology.—The condition is directly referable to lack of oxygen. There is considerable difference among individuals as regards liability to the appearance of symptoms at low atmospheric pressures, some suffering earlier and more than others. The immediate effect of exposure to such pressures is to cause rapid concentration of the blood and therefore a relative increase of the ratio of the hæmoglobin to the volume. A 10 per cent. rise in the hæmoglobin ratio may occur after 20 minutes' exposure. This serves as a compensation for the oxygen-want of the tissues, and its occurrence is associated with a disappearance or amelioration of the initial symptoms of oxygen-want. In those who remain at a bearable high altitude many weeks, some degree of acclimatisation occurs, and this is associated with hyperactivity of the blood-forming organs and a true erythræmia. The anoxæmia produces a hyperglycæmia, and there is at first an increased alkalinity of the blood from increased ventilation which subsequently lessens.

Symptoms.—*Mental effects* occur most importantly when rapid ascents to high altitudes are made in aviation, and consist of a gradually increasing dulling of perception, of which the subject is usually unaware. There is an increasing inaccuracy and lethargy of mental functions with a tendency

to torpor and loss of memory. The skilled photographic observer takes eighteen photographs upon the same plate, the observer throws his valuable notes overboard, the pilot makes for a wrong destination or goes to sleep, and the fighting scout forgets to go into action. On return to land a muddled and confused memory of what has happened during the flight is all that remains. Lesser degrees of this condition have led to great errors in judgment, foolhardiness, apparent cowardice and irresponsibility in military aviation. So insensibly does this mental paralysis come on and so deep may be its effect before its presence is realised, that in Tissandier's balloon ascent in 1875, though provided with oxygen apparatus, all three aeronauts were paralysed beyond movement before realising the necessity for using it, and two of them lost their lives. Diminution of auditory perception becomes so great at high altitudes that the aeroplane engine becomes almost inaudible.

Respiratory effects.—At an altitude of 12,000 feet, nose-breathing ceases, and above this height the breathing deepens into hyperpnœa, which may be most distressful and may be periodic. The dyspnœa is greatly increased on exertion and is accompanied by cyanosis. Even such acts as talking and using a pressure pump may greatly increase the dyspnœa.

Muscular weakness.—Accompanying the mental lethargy is an increasing condition of muscular weakness. The slightest exertion is hard work. The machine is difficult to fly at very high altitudes, and the marksman shoots badly, and the mountaineer becomes incapable of taking exercise.

Other symptoms which may occur are—(1) headache, which may be very intense and which is very usually met with in prolonged exposure to high altitudes, as in mountain climbing; (2) spasmodic gulping accompanying the hyperpnœa; (3) fainting on exertion; (4) vomiting; and (5) hæmorrhage in the form of epistaxis, both of which are rare; and (6) frequency of micturition, which is common.

The mental effects are most conspicuous in aviators who had to make prolonged flights at very high altitudes during the Great War before the regular use of the oxygen apparatus. The dyspnœa, headache, and muscular effects have been most troublesome in mountain ascents where exertion is unavoidable.

Death has occurred only in balloon ascents to gain a great altitude, and it occurs very rapidly, and is preceded by general muscular paralysis. Glaisher and Coxwell survived 29,000 feet by a lucky chance after complete paralysis of the limbs had set in. Sivel and Croce-Spinelli died at a height of 27,500 feet, while Tissandier, who was with them, survived. The after-effects of exposure to high altitudes has been well described by Birley, who, after observing many flight landings after high patrols during the Great War, writes: "The gait of the men on landing is unsteady and laboured. Reports are laboriously made out (there being a general disagreement as to what was seen and done). Tempers are short, every one looks and feels tired, and the idea uppermost in the mind is to lie down and go to sleep. Severe frontal headache is common; it may persist until the following day and at times proves incapacitating. Appetites are poor and spirits are depressed. It is easy to understand that a repetition of this kind of work over any length of time was rapidly productive of deterioration of mental and physical well-being."

Remarkable individual tolerance to anoxæmia occurs in some subjects,

but this tolerance tends to disappear with repeated long exposure. Physical fitness and training increase toleration up to a certain point, whereas unfitness and especially digestive disturbances lower tolerance, and the latter are apt to induce vomiting.

Treatment.—Since the symptoms are due solely to lack of oxygen they can be entirely avoided by the use of a portable apparatus to deliver the necessary oxygen by all those who have to encounter an altitude of over 15,000 feet. Professor Dreyer's apparatus is portable, compact and satisfactory, and its essential feature is the regulation of oxygen delivery by an aneroid controlled valve, so that the amount of oxygen delivered varies in inverse proportion to the barometric pressure of the atmosphere surrounding the instrument and consequently in direct proportion to the altitude.

When symptoms have developed, the immediate treatment requisite is the cessation of exertion, the provision of oxygen if available and a speedy return to a lower altitude.

SEA-SICKNESS AND ALLIED CONDITIONS

Definition.—A disorder of the central nervous system produced by an unaccustomed and irrelative stimulation of the afferent organs which subserve the orientation and sense of movement of the body in space, namely, the eyes, the labyrinths, the splanchnic sensorium and the common sensorium of skin and muscles. This stimulation may occur when the body as a whole is subject to continuous movement which does not allow of continuous correct ocular and vestibular correlation of self and external objects, as in train-sickness and dancing-sickness, and more especially when it is subject to alternating movements which destroy the correspondence between the afferent impressions reaching the nervous system from those organs, as in sea-sickness and swing-sickness. The symptoms of this disorder are expressed as a feeling of spatial insecurity and visual disorientation, vertigo, diplopia, headache, anorexia, nausea and vomiting, pallor, lowering of blood-pressure and prostration.

Pathology.—Animals are as liable to the disorder as is man. Early infancy is immune from the affection, since the orienting mechanism has not attained physiological activity; and old age is relatively immune, probably from lessening irritability of the nervous system. Individual hypersusceptibility and individual immunity are very common, and the readiness with which toleration is acquired by training varies greatly in different people. Personal immunity is for the most relative only, for there are few who can pass through excessive and prolonged stimulation without developing some of the characteristic symptoms. The development of tolerance by habitude varies greatly. Some develop tolerance readily, others with great difficulty. Twelve years of continuous sea-going passed before any tolerance was developed in 2 cases under my observation, and Admiral Nelson never acquired any tolerance. An attack of sea-sickness resembles closely an attack of migraine, and again it resembles acute cerebellar irritation, and again the symptoms which follow chloroform and ether anæsthesia and alcohol poisoning, for the reason that in all these conditions it is the nervous mechanism of orientation which is especially disturbed. The subjects of

migraine are almost invariably particularly bad sailors and train travellers, and the symptoms of their attacks of sea-sickness and train-sickness often take the pattern of the migrainous attack. The importance of the factor of ocular disorientation is well shown by the fact that "sea-sickness" may occur in a susceptible subject when he is stationary but when the objects around him move in undulatory fashion, as from the movements of the waves when he is upon a pier and when he witnesses sea movements as a stage effect. The vestibular irritation is shown by the vertigo and ataxy, diplopia and vomiting, and by the high potentiality of short angular movements in causing the symptoms, as from a small boat anchored in a swell, or an observation balloon anchored in a puffy wind. The importance of the splanchnic sensation when the vessel "lifts" and "scends" in producing nausea and adding to the general misery is obvious to any one who has experienced sea-sickness. It is this factor which tends to cause an attack of sea-sickness during sleep when the ocular and vestibular mechanisms are relatively at rest.

The precautions which tend to obviate sea-sickness are those which tend to eliminate or lessen the essential factors in its production. A position amidships where the angular movements are least, a supine decubitus which most protects the semicircular canals from stimulation, and which removes the muscular sense element, and in a cabin which moves more or less with the body, and therefore produces little ocular disorientation, is the one best calculated to avert or lessen the disorder. A gyroscopic cabin which removes all the factors except the "lift" and "scend" element is said to obviate the disorder even in the most susceptible subject.

There are many adjuvant factors which are important but not essential, such as apprehension from previous experience, cold, expectant attention, the smell of the ship, dyspepsia, and the presence of others suffering from sea-sickness.

Symptoms.—The initial symptoms are a loss of the usual feeling of well-being, accompanied by a vague feeling of cephalic, ocular and epigastric discomfort. Salivation, gaping and yawning follow, with irregularity of respiration, flatulency, pallor of the face, and a sense of squeamishness, as though at any moment vomiting might occur.

In the fully developed attack it is convenient to divide the symptoms into two groups—cephalic and gastric; but though in different subjects one or the other group may dominate the aspect of the attack, yet few persons suffer from the one group of symptoms to the complete exclusion of the other. The cephalic group comprises ocular distress, diplopia, which may be severe though transient, giddiness, headache, depression, and mental despondency and apathy. These may persist for a very considerable time after the patient goes ashore.

The gastric symptoms consist of nausea, retching and vomiting, which are often most violent and distressing, the vomit ultimately consisting of a thin, bile-stained fluid. There is complete anorexia, and in severe cases nothing can be retained in the stomach. Constipation is often obstinate.

The general constitutional effects of prolonged sea-sickness may be very severe. There is a general condition of collapse. Alternate heats and chills, with frequent chattering of the teeth and shivering, pervade the system; the eyes are dull, and may be bloodshot from straining; the countenance

becomes shrunken, pale and perhaps greenish, inexpressive and dejected. The cardiac action is depressed, the blood concentrated, the body desiccated, and little urine is passed. The pulse and respiration are quickened, the skin is cold and either dry or clammy, the tongue is moist and coated, and both the breath and the urine are likely to contain acetone bodies. Hebetude is always marked, and in severe cases the mind may be utterly indifferent to the surroundings and no consecutive train of thought can be pursued. There is a general feeling of bodily soreness and weariness and a sense of exhaustion.

Course and Prognosis.—The symptoms usually subside rapidly when the voyage or other movement causing the condition is over, but sometimes both the cephalic and gastric symptoms persist for a time, and the patient is "good for nothing" until he has had a night's sleep. In persons taking long sea voyages, the symptoms usually lessen in a few days, reaction sets in with a return of appetite, and convalescence is complete within a week, but symptoms are liable to return with an onset of rough seas. Some persons, on the other hand, never lose the symptoms until the voyage, however long, is over, and these may be reduced to a piteous condition of bodily weakness, from which subsequent convalescence is slow. Death appears never to have occurred even in the most severe condition of bodily depression and starvation from sea-sickness. Apart from the prolonged convalescence which may be required in severe and long-lasting cases, there seem to be no harmful results from sea-sickness. It has been held to have a salutary effect upon subsequent health since ancient times. In pregnant women it does not have any tendency to cause miscarriage.

Treatment.—*Prophylaxis.*—To avoid sea-sickness a susceptible subject should, for a few days before taking to the sea, eat sparingly, avoid alcohol and over-fatigue, take regular exercise and carefully attend to any condition of dyspepsia and constipation, and partake of a good wholesome meal some two hours before going on board. He should secure a berth amidships, lie supine with the head low, and keep warm. Some persons find a closed cabin insufferable, and are better on deck in the open air. The administration of bromides some hours before sailing is often of signal service, and this will often lessen the cephalic symptoms when an attack has developed. Chlorotone also is very valuable both as a prophylactic, when it should be taken just before sailing, and as a remedy during the attack. Combinations of these two remedies are very useful, and there is at least one patent remedy, of which the basis is monobrom-camphor and chlorotone, which is very efficacious.

During the attack it is essential to keep warm and as quiet as is possible, and avoid any source of further irritation of the organs of orientation; to quiet the irritation of the nervous system with bromides and chlorotone; to secure sleep, to which end barbitone or adalin is very useful; to prevent acidosis and to see that the patient is fed. With severe and prolonged vomiting, anorexia and prostration it may be difficult to secure these ends. Swallowing food must be insisted on, and the administration of very small perfectly dry meals, such as cold chicken and biscuit, will often break the anorexia and vomiting. A severe case should always be brought into the open air on deck after four days in the cabin. Acidosis should be combated by the alkaline carbonates. Alcohol and aromatic carminatives are sometimes valuable.

HEAT-STROKE AND THE EFFECTS OF HEAT

Under this heading are included those types of illness caused by exposure to a high atmospheric temperature. They are classified as—(1) heat exhaustion; (2) heat hyperpyrexia (heat-stroke or sun-stroke); (3) the gastric type of illness; and (4) the choleraic or gastro-intestinal type.

Ætiology.—*Exposure to high temperature.*—Cases commonly occur amongst those exposed to the sun in the hot seasons of a tropical climate; but the high temperature of the air in a dwelling, or the excessive heat to which stokers are exposed on board of ships, or, indeed, any prolonged exposure to a high atmospheric temperature, whatever its nature, may cause any of the types of heat-stroke. When the shade temperature reaches 110° F., danger occurs, and with each degree rise above this limit an increasingly larger number of cases results. The effect of heat exposure is cumulative in action, and it is a succession of hot days which is followed by a large number of cases of heat-stroke. A comparison by Willcox of the case incidence curves with the temperature curves in the Mesopotamian campaign indicated a delay of a few days in the rise of the former. An individual exposed to heat for one or more days may not be taken ill until the evening or early morning, when the temperature has fallen considerably, the cumulative effect of the exposure gradually overcoming the body resistance. Since the temperature in the sun greatly exceeds that in the shade, exposure to the sun's rays is a very important exciting cause. In the hot seasons of tropical countries this danger is well known, and exposure to the sun is avoided, as far as possible. It has not been shown that any rays of the sun other than the heat rays have a special significance in the causation of heat-stroke.

Climate.—Tropical climates in seasons when the shade temperature exceeds 110° are associated with the various forms of heat-stroke, and heat waves in any climate, if the temperature is sufficiently high, act as causes of illness. The absence of shade from the sun is an important factor, and heat-stroke is specially associated with hot climates of countries where flatness and absence of trees and vegetation are marked, as, for example, in Mesopotamia and the country round the Persian Gulf, and desert regions generally, as in the Sahara Desert in Africa. In countries where, during the hot season, there is little fall of the temperature at night, the danger from heat-stroke is increased.

Humidity of the atmosphere is an important predisposing factor. If this is high, heat loss is retarded, and there is greater liability to heat-stroke.

Stagnation of air.—Free currents of air promote the evaporation from the skin and protect by increasing heat loss. The great protective value of electric fans and punkahs in dwellings is due to this cause. It is important to remember, however, that when the temperature is very high, currents of hot air may do more harm than good, and for this reason in tropical countries, houses provided with fans should be kept closed during the heat of the day, in order that the hot air may be excluded as far as possible. The "Kata" thermometer, introduced by Professor Leonard Hill, F.R.S., records the rate of heat loss from evaporation of a wet

bulb, and is a valuable guide in estimating the dangers from heat-stroke in different situations, such as the wards of hospitals.

Dwellings.—Thick walls of non-conducting material, such as stone, brick, or dried mud are protective, and it is important that the roofs of dwellings should be thick, so as to keep out the heat from the sun's rays. A tent, even of double canvas walls and roofs, affords only poor protection.

Persons of any age are subject to heat-stroke if the exposure is sufficiently great. The case mortality is higher in those over 40. Race is a very important factor. The natives of tropical countries are rarely affected by heat-stroke, unless some complicating disease, such as malaria, is present. White races unaccustomed to tropical climates are specially susceptible to the effects of heat exposure. Exertion is an important predisposing cause. Heavy physical exertion in temperatures over 110° is very dangerous.

Predisposing diseases.—Any disease causing pyrexia, such as malaria, sand-fly fever, enteric and paratyphoid fever, typhus fever and small-pox, predisposes to heat-stroke.

Intercurrent diseases.—In a high percentage of cases the heat hyperpyrexia supervenes in the course of another disease, especially malaria. Cases of febrile disease may be suddenly complicated by hyperpyrexia if exposed to great heat, and special precautions are necessary to prevent this.

Pathology.—The symptoms of heat-stroke in its various forms all point to an auto-intoxication. The effect of high temperature on the brain and central nervous system is to diminish its functional activity, and likewise the excretory organs, such as the liver and kidney, are undoubtedly impaired in their excretory power. In addition, owing to the effect of heat on the muscles and tissues of the body generally, there must be an increased production of toxic substances, due to protein katabolic changes. These factors all tend to produce a marked auto-intoxication, which explains many of the symptoms of heat-stroke. Indican is usually present in the urine in considerable excess, and is evidence of an auto-intoxication. Acetone and diacetic acid are not found in appreciable excess in the majority of cases, though in a small percentage they are present in moderate degree. The auto-intoxication cannot, therefore, be regarded as an acidosis. It has been recently shown by Dr. W. Cramer that beta-tetra-hydro-naphthylamine will cause hyperpyrexia in animals, and it is likely that substances having a similar action are produced as the result of the heat on the tissues. Suppression of sweating has been shown by Dr. K. G. Hearne to be an important factor in the hyperpyrexia cases, the paralysis of the sweat secretion by the intense heat leading to a rapid rise of body temperature. In hot climates, the administration of atropine may be followed by hyperpyrexia from a similar cause. Suppression of sweating does not explain the causation of the gastric and choleraic type of heat-stroke, nor of heat exhaustion. It has been stated that heat-stroke is due to a bacterial infection; but there is no recent evidence to support this view. In the Mesopotamian campaign a large number of blood examinations were made during life in cases of heat-stroke, but all gave a negative result.

Rigor mortis occurs early, and putrefactive changes set in within a few hours of death. Edema and general hyperæmia of the brain and lepto-

meninges occur, and the nerve cells in the grey matter show marked degenerative changes. Petechiæ occur in the skin and mucous membranes in severe cases. The right side of the heart is dilated, and venous congestion is marked in all the organs. Signs of intercurrent diseases, such as malaria and typhoid, may be present.

Prophylactic Treatment.—Adequate protective covering for the head by thick pith topees or good cork helmets is essential. Spinal pads for protection of the spinal cord are valuable. The clothing should be light and loose and not too thin. Hand-fans and umbrellas are of value. A large amount of water should be drunk by those exposed to great heat, as so much moisture is lost by the skin in regulating the body temperature. Alcohol should be avoided during the heat of the day. Constipation should be guarded against, as it predisposes to the effects of heat.

Symptoms, Prognosis and Curative Treatment.—1. **HEAT EXHAUSTION.**—The onset is sudden, with weakness, giddiness, faintness and inability to walk. A mild pyrexia of 102° or 103° F. occurs, lasting 2 or 3 days. The pulse is rapid and weak, and some cardiac dilatation is usually evident. If early treatment is adopted, the symptoms quickly improve; otherwise, there is a great risk of the supervention of hyperpyrexia.

The treatment consists in removal from heat, rest in bed and the administration of aperients.

2. **HEAT HYPERPYREXIA.**—The onset may be sudden, with rapid rise of temperature, coma and convulsions. In other cases, the onset is preceded by malaise, headache, restlessness and sometimes nausea or vomiting. Frequency of micturition and urethral pain may occur. The temperature is somewhat raised—to 100° or 102° F. or so—and the skin hot and dry. These premonitory symptoms may last for a few hours, sometimes as long as 48, when the temperature rises to 110° F. or more, and mental excitement and delirium supervene. Coma and stertorous breathing now occur, and the face is flushed and cyanosed, the conjunctivæ being congested. The pupils are commonly dilated in the early stages and contracted in the comatose condition. Parotitis may occur, and petechiæ of the skin may be present in severe cases.

Albumin is frequently present in the urine in small amount in acute cases. An excess of indican is usual, and in some cases acetone and diacetic acid occur. Fibrillary twitchings of muscles and convulsions usually result, and the breathing is frequently Cheyne-Stokes in character. Incontinence of urine and faeces occurs with the coma, and death rapidly results, unless the temperature is reduced. Marked cardiac dilatation, often associated with a systolic murmur, is present. Bronchitis and pulmonary congestion sometimes occur, and pulmonary œdema is a terminal event. In the acute stage the knee-jerk is almost always absent, and does not return until the symptoms have cleared up.

Defective articulation (anarthria) occasionally occurs as an after symptom, and sometimes nystagmus, or squint, with diplopia has been observed. Multiple neuritis, with weakness and wasting of the extensor muscles of the legs, is a rare late complication. After the subsidence of the hyperpyrexia, a pyrexia up to 102° or 103° F. may persist for several days, and is due to the auto-intoxication present, no organism being found in the blood in the uncomplicated cases. For some weeks after the subsidence of the tempera-

ture there is great liability to a recurrence of heat hyperpyrexia, and the utmost care must be taken to avoid exposure to heat.

Sequelæ.—Cardiac dilatation may last for some days or weeks after an attack. There is a great susceptibility to heat for a long period after an attack, and headache may follow slight exposure, so that residence in a cool climate is advisable for some years afterwards. An abnormal mental condition, amounting in some cases to insanity, may result. Persistent nervous symptoms, the result of actual organic changes in the brain or cerebellum, may remain. The presence of the knee-jerks is a valuable prognostic sign; if they remain absent there is danger of a recurrence.

Treatment.—The patient should be placed in cool surroundings and hydro-therapeutic measures immediately adopted. Spraying with ice-cooled water, the patient lying on a bed with a rush mattress, so that there is free circulation of air round the body, is the most convenient method. Ice should be applied to the back of the neck and head. Rectal injections of ice-cold water are of value. Should the hyperpyrexia not quickly subside, or should it not be readily controlled, an intramuscular or intravenous injection of a solution of quinine bihydrochloride, *grs. x*, should be given. Blood film examinations should always be made immediately when hyperpyrexia occurs, and if these show a malarial infection the quinine treatment should be continued, daily injections being given for 3 or 4 days, and afterwards an oral course. Convulsions are best treated by a venesection of 10 to 20 ounces, and rectal injection of ice-cold water containing 2 drms. of bicarbonate of soda to the pint. In cases with convulsions it is not advisable to give intravenous saline after venesection, for the intravenous injection may cause recurrence of the convulsions. In some cases morphine hypodermically or inhalations of chloroform may be required. Cardiac failure should be treated by digitalin, strychnine, adrenalin or pituitary extract hypodermically. Failure of respiration should be treated by artificial respiration, and oxygen bubbled through alcohol may be administered.

3. THE GASTRIC TYPE.—In this insidious type of illness for several days the patient will suffer from restlessness and mental irritability, nausea and occasional vomiting. The face is flushed and the mouth temperature normal; but the rectal temperature may show a rise of a degree or two. The liver shows some enlargement, and the knee-jerks are lost. In many of these cases after 4 to 10 days' illness a sudden hyperpyrexia occurs, which is often fatal.

Treatment.—This consists in keeping the patient as cool as possible, free purgation, a lacto-vegetarian diet, and rectal injections of ice-cold water containing bicarbonate of soda, 2 drms. to the pint, and the administration of 30 grains of sodium bicarbonate every 3 hours; by these means hyperpyrexia is avoided.

4. GASTRO-INTESTINAL OR CHOLERAIC TYPE.—In this form of illness the onset is sudden, and marked collapse is present. The temperature is raised to 100° or 102° F., and vomiting and diarrhoea occur. The face is pale, the skin clammy and the eyes sunken. The knee-jerks are lost. The stools are watery, and free from cholera organisms. Death usually occurs after a 3 or 4 days' illness.

Prognosis.—This is very grave.

Treatment.—This consists in protection from heat, the administration

362 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

of normal saline subcutaneously or intravenously, and the administration of suitable cardiac stimulants hypodermically.

HEAT CRAMPS.—Attacks of heat cramps occasionally occur in persons who perform muscular exercises while exposed to high temperatures. The condition occurs in stokers on board ship, and in furnace workers. The muscular spasms occur in the calves, arms and sometimes the abdominal muscles, and are severe and very painful. They may last from 12 to 36 hours, and are followed by soreness and weakness.

ALCOHOLISM

The term "Alcoholism" denotes the toxic effects, whether acute or chronic, resulting from the ingestion of alcohol in some form. The subject may be conveniently divided into—(1) Acute alcoholism; (2) chronic alcoholism; and (3) delirium tremens (*see* pp. 367, 1701).

1. ACUTE ALCOHOLISM

Pathology.—The mucous membrane of the stomach may be found red and congested, the brain and viscera are usually congested and the right heart filled with dark fluid blood. Alcohol may be detected in the stomach contents, and also in the blood and cerebro-spinal fluid.

Symptoms.—When a large quantity of alcohol is taken the symptoms come on in a few minutes. The face is flushed and often slightly cyanosed. There is mental disturbance and confusion of ideas, with excitement. The speech is thick. The gait is staxic, and muscular inco-ordination marked. After a short period, in severe cases, the patient becomes stuporose and later unconscious and comatose. In the unconscious stage of alcoholic poisoning the patient may usually be roused to some extent so as to give an incoherent reply. The comatose condition may gradually pass away and the patient recover. The pupils are generally dilated, and in severe cases may not react to light. The pulse is full, and the respirations are deep until the late stages. The breath generally has the odour of alcohol; but it should be borne in mind that frequently alcohol is administered as a restorative to patients in an unconscious state, and the smell of the breath may be due to this cause.

In some cases death occurs—(1) from shock, which may occur early when a large quantity of concentrated alcohol is taken; (2) from syncope, preceded by prolonged coma; and (3) after an apparent recovery from a comatose state, a sudden fatal syncope may occur.

Diagnosis.—This is of the greatest importance, since serious consequences may result if a diagnosis of acute alcoholism is made in conditions due to other causes. It is often impossible for an exact diagnosis to be made until the patient has been kept under observation for some little time, and this precaution should always be taken where there is any doubt as to the diagnosis.

Conditions simulating the coma of alcoholic poisoning are:

1. *Cerebral lesions.*—(a) Traumatic lesions, such as fracture of the skull, concussion, etc. (b) Vascular lesions, such as hæmorrhage, thrombosis

or embolism. (c) **Inflammatory conditions**, such as acute meningitis, *e.g.* epidemic cerebro-spinal meningitis, and encephalitis lethargica. (d) **Cerebral tumour**, with sudden coma. (e) **Epileptic coma**, especially that occurring in status epilepticus. (2) **Auto-intoxications**, *e.g.* uræmia, diabetic coma, and the coma of acid intoxications. (3) **Toxæmic conditions**, *e.g.* the coma occurring in typhoid fever, influenza, septicæmia of various kinds, malaria, sleeping sickness, etc. (4) **Toxic conditions**, resulting from other poisons producing a state of coma, *e.g.* opium and its alkaloids, sulphonal, veronal, chloral, chloroform and a large number of other narcotic drugs.

An exact diagnosis can only be made by carefully considering the history of the case, and by a very careful physical examination. Examination should be made for signs of injury, or evidence of a cerebral lesion, such as hemiplegia, papilloedema, cranial nerve paralysis, unequal pupils, etc. The urine should be examined for albumin, sugar, acetone, diacetic acid, casts, etc. A careful clinical examination should be made for evidence of toxæmic conditions, such as pyrexia, enlarged spleen, rashes, abnormal conditions of the blood, etc. The presence of other poisons than alcohol can in some cases be suspected by the symptoms, *e.g.* in opium poisoning the pupils are generally pin-point, the skin moist, and the breathing slow and shallow. An exact diagnosis can be made by the analysis of the gastric contents or of the urine, when alcohol or other poisons may be detected. Alcohol can be found in the blood, urine and cerebro-spinal fluid of persons suffering from acute alcoholism.

Recent toxicological research has shown that alcohol is always present in the blood and urine during the acute stage of alcoholic intoxication. The amount present is usually over 0.1 per cent. It has been suggested that these tests should be made use of for the medico-legal diagnosis of "drunkenness." In the present state of our knowledge, no exact percentage of alcohol in the blood and urine can be fixed as the precise limit between sobriety and drunkenness for medico-legal purposes, though excessive percentages of alcohol strongly indicate the diagnosis of drunkenness or acute alcoholism.

Treatment.—The stomach should be washed out by means of a soft stomach tube and funnel, and about a pint of hot strong coffee introduced. In severe cases strychnine may be given hypodermically, *e.g.* $\frac{3}{50}$ grain every 4 hours.

DIPSOMANIA is a form of acute alcoholism which manifests itself in periodic attacks of indulgence in great alcoholic excess. Between the attacks alcohol is often entirely abstained from. In dipsomania there is a paroxysmally recurring overwhelming desire for excess of alcohol, which must be regarded as an abnormal mental condition not induced by the previous taking of alcohol.

PSEUDO-DIPSOMANIA is a condition in which paroxysmal attacks of alcoholic excess occur, these attacks being induced by the ingestion of alcohol. There is no overwhelming craving for alcohol; but the accidental taking of alcohol from any cause is the starting-point of a drinking bout.

Treatment.—In *dipsomania*, if the patient is seen during an attack, rest in bed and special nursing supervision are essential. A dose of apomorphine hydrochloride hypodermically of $\frac{1}{10}$ gr. should be given, unless there is marked cardiac weakness. This will probably induce vomiting, and sleep for some hours usually follows. Afterwards the craving has usually abated, but further small doses of apomorphine hydrochloride, *e.g.* $\frac{1}{30}$ gr., may be

given for an hypnotic effect. This dose may be repeated after a few hours for three or four doses. In the premonitory stages of dipsomania, when the craving is commencing, one or two hypodermic doses of $\frac{1}{16}$ gr. of apomorphine hydrochloride will often induce slight nausea, followed by sleep, and on awakening the craving for alcohol will have disappeared.

In *pseudo-dipsomania* the treatment during an attack is similar to that of dipsomania.

Total abstinence is essential in the intervals between the attacks in both conditions. Often a complete change in the surroundings and mode of life will be effectual in preventing a recurrence of the attacks. Psycho-therapeutic treatment has been of value in some cases.

2. CHRONIC ALCOHOLISM

In this condition alcohol is taken over long periods in amount to produce toxic effects without necessarily the manifestation of the symptoms of acute poisoning described above.

Ætiology.—An unstable nervous system is commonly the basis on which habitual alcoholic excess develops. Worry, over-work, grief, disappointments, etc., often lead to the resort to alcohol as a temporary relief, and so the habit of alcoholic indulgence becomes implanted. *Occupation* is an important factor. Those engaged in the sale of alcoholic drinks are frequently unable to resist the temptation of the alcoholic habit. Occupations involving great mental or bodily strain, long hours and excitement often predispose. *Heredity.*—There is commonly a family history of alcoholic excess; but it is the inherited condition of an unstable nervous system which may cause slight indulgences to lead to the formation of the alcoholic habit. *Habit.*—In predisposed persons the alcoholic habit is quickly established, and for this reason medical practitioners must use the greatest caution in prescribing alcohol for patients except in special cases.

Pathology.—The important constituent of alcoholic drinks is ethyl-alcohol. Spirits (brandy, whisky, rum, gin, liqueurs, etc.) contain from 40 to 60 per cent. of alcohol. Wines, such as port, sherry, madeira, contain from 15 to 25 per cent. Light wines, such as claret, hock, champagne, burgundy, contain from 10 to 15 per cent. Light beers contain from 2 to 5 per cent. of alcohol. In the case of spirits, higher alcohols, such as propyl-butyl, and amyl-alcohols (constituents of fusel oil), may be present in small amount. These are much more toxic than ethyl-alcohol; but researches have shown that they are not present in a sufficiently high percentage to be really important toxic factors. The presence of esters in wines and spirits adds to their flavour and bouquet without increasing their toxicity. It may be accepted that the determining factor in the toxicity of alcoholic beverages is the percentage of ethyl-alcohol present. Medicated wines often contain quite a high percentage of alcohol.

Alcohol in small quantities may have a slightly stimulating action on the gastric digestion and on the heart, and when a certain degree of tolerance is established alcohol may have a definite food value; but there is abundant evidence to show that the effect of alcohol in appreciable quantities is of a toxic nature. Thus there is a depressing action on the nervous system, and judgment and perception become quickly impaired. In large quantities

alcohol is a narcotic poison and also it is a definite tissue poison, producing degenerative changes in the liver, heart, kidneys, blood vessels and nervous tissues. There is no doubt that the toxic effects of alcohol are more marked if it is taken on an empty stomach, or with an insufficient amount of food in the dietary.

The combination of alcohol with other poisons, *e.g.* arsenic, may increase the toxic effect of the latter. This was well shown in the epidemic of beer poisoning in 1900, where the presence of relatively small quantities of arsenic in beer caused in a number of cases severe symptoms of chronic arsenical poisoning.

Circulatory system.—In the blood vessels the result of chronic alcoholism may be atheromatous change. In the heart fatty degeneration is common, and this is often associated with brown atrophy. Fibrous myocarditis may result from atheromatous changes, causing obstruction in the coronary arteries. Cardiac dilatation may occur as a consequence of the myocardial changes, or of atheromatous valvular changes. *Liver.*—Fatty degeneration of the liver cells occurs, and this is often accompanied or followed by cirrhotic changes (see pp. 383, 633). Alcohol may produce an enlarged, yellow, fatty liver, which is characteristic of excessive beer-drinking, or an atrophic cirrhosis—the so-called hob-nailed liver—such as follows excessive indulgence in spirits. *Kidneys.*—Alcohol may cause fatty degeneration and necrosis of the renal epithelium, and it is undoubtedly an important factor in the causation of chronic parenchymatous nephritis and chronic interstitial nephritis.

Nervous System.—The atheromatous changes occurring in the cerebral vessels lead to degenerative changes in the cells of the grey matter; but there is no doubt that alcohol has also a direct effect upon them, so that the nerve cells in the cerebral cortex show the usual appearances resulting from a direct tissue poison, *e.g.* swelling of the nerve cells with vacuolisation, pigmentation and chromatolysis, and also marked degeneration of the apical processes. In the nerve fibres degenerative changes are seen in the axis cylinders, and also interstitial changes are common.

Symptoms.—The tongue is usually furred, and morning retching is common. The appetite is poor, and complaint is made of abdominal discomfort and flatulence. There may be pain and discomfort in the epigastric and left hypochondriac regions, due to gastritis, or discomfort in the right hypochondrium, due to hepatic congestion and perihepatitis. There may be looseness of the bowels, and hæmorrhoids are common. The liver may be enlarged and somewhat tender, and this is sometimes accompanied by splenic enlargement. In old-standing cases symptoms of alcoholic cirrhosis, such as slight jaundice, ascites and intestinal catarrh, are likely to occur (see Cirrhosis of Liver). The venules on the face become dilated, and the patient may show the characteristic appearance of the face and nose such as occurs in acne rosacea. The eyes are prominent and may show some conjunctival injection, with slight bile staining of the sclerotics. The heart is often dilated, and as a result œdema of the legs may occur. The urine often contains albumin, with possibly some granular and hyaline casts.

In chronic alcoholics there is undoubtedly a lowered resistance to tuberculosis, and a careful look out for signs of pulmonary tuberculosis should be kept.

Nervous system.—The mind becomes affected early. The patient is

irritable, and the judgment and will are impaired. Loss of memory is a characteristic symptom. Change in the moral character is common. Tremor of the hands and tongue is frequent, and unsteadiness of the muscles in performing any action is often seen. Symptoms of peripheral neuritis are likely to occur, such as pains and numbness in the limbs, hyperalgesia, tenderness of the calves and weakness of the legs. In severe cases, foot-drop and even wrist-drop may occur, there being great muscular weakness and loss of the patellar reflex. Mental symptoms, such as hallucinations and delusions, are common, and in advanced cases a condition of dementia may result.

Korsakoff's psychosis is a term which has been applied to a combination of polyneuritis with a characteristic mental condition due to alcohol. A condition of low delirium may occur, and hallucinations and even delusions are common. There is loss of memory for recent events. Marked symptoms of polyneuritis develop, and paralysis of cranial nerves may occur.

Epilepsy sometimes occurs in cases of alcoholism. This may be due to the toxic effect of alcohol, the gradual withdrawal of which effects a cure. In some cases the sudden withdrawal of alcohol in patients accustomed to large doses over a long period may induce epileptiform attacks. Of course an epileptic patient who indulges in alcoholic excess is thereby rendered more liable to an increased frequency of recurrence of fits.

Treatment.—This depends on the form of chronic alcoholism present. It is usually advisable in this condition to place the patient in a nursing home or special institution, where there will be strict medical and nursing supervision. The patient should understand that the object of the treatment is to remove his desire for alcohol, and it should be impressed upon him that his only safeguard against relapses is continued and entire abstinence. Rest in bed for the first week or so of the treatment is advisable. Sudden withdrawal of alcohol is inadvisable in patients who have acquired a high degree of tolerance, and who have been taking large quantities over a long period. In such cases a gradual reduction of the daily dose is to be recommended, so that at the end of a week complete withdrawal has been effected. At the commencement of treatment a purgative is advisable. The diet should be light and nutritive—fruit, vegetables and milky foods being freely given. Meat and meat soup and highly flavoured cheeses are best avoided. Smoking should be given up, especially in patients in whom it induces a desire for alcohol.

A tonic mixture of cinchona and gentian containing small doses of atropine and strychnine may be given with advantage 5 times daily every 3 hours, e.g.

Liq. atrop. sulph., ℥ ½.
 Liq. strychnin., ℥ i.
 Tinct. cinchonæ co., ℥ xx.
 Glycerin., ʒss.
 Inf. gent. co. ad. ʒss.

In addition a mixture of strychnine and atropine is given hypodermically three times a day after meals. The dose of liquor strychnine begins at 2 minims and the dose of atropine begins at 1 m. of a solution of atropine sulphate (1 grain to 1 ounce). The strychnine is increased in dose by 1 m. of the solution every other day until a maximum of 5 minims is reached. The

dose of the atropine solution is increased by 1 minim every other day up to a maximum of 6 minims of the weak solution (1 grain to 1 ounce). After the end of the third week the doses of strychnine and atropine hypodermically are gradually reduced, so that at the end of the sixth week the hypodermic treatment is discontinued. If patients are specially susceptible to the action of atropine it is advisable not to give this drug except in the mixture by the mouth, and only then if it is well borne.

The medicinal treatment should, after the first week, be accompanied by gentle open-air exercise, fatigue being avoided. It is important that congenial occupation should fill up the day, and country surroundings and open air are essential. It is important that insomnia should be avoided by suitable treatment. In debilitated patients general massage and rest in the open air are helpful. In the case of many patients a course of treatment of 6 weeks to 2 months is sufficient, and then the ordinary occupation may be resumed. Every case must of course, be treated according to its special requirements.

3. DELIRIUM TREMENS

This is a condition always to be borne in mind in chronic alcoholics. The sudden withdrawal of alcohol, or the occurrence of any accident or acute illness may cause symptoms of this condition to develop. For description of this complication, see p. 1701.

ARSENICAL POISONING

Arsenic is the most important of the irritant poisons, and owing to the almost tasteless property of many of its compounds and preparations it is perhaps the commonest poison used for homicidal purposes. It used to have a reputation as a cosmetic, and was added to face powders, skin lotions, etc. It is practically never used now for such purposes.

Occurrence.—*White arsenic*, i.e. arsenious acid, or arsenious anhydride, As_2O_3 , is the most important of the compounds of arsenic. It occurs in the form of a white powder, or in lumps like glass or porcelain (vitreous arsenic). The powdered form resembles powdered sugar or flour, and when mixed with solid food is tasteless. It is slightly soluble in cold water, an ounce of cold water dissolving from a half to 1 grain. In boiling water it is twelve times more soluble, from 6 to 12 grains dissolving in an ounce. Alkaline solutions readily dissolve arsenic. If white arsenic is sold to the public the law requires that it should be mixed with soot or indigo to colour it. It is used in the composition of sheep dip, arsenical soap, rat poisons, etc.

Metallic arsenic is a black powder and is very poisonous, and is used for killing flies. *Copper arsenite* (Scheele's green) is bright green in colour, and used to be employed for colouring wall-paper, toys, floorcloth, fabrics, etc. Its use for such purposes has fortunately been abolished. *Arsenious sulphide*, or orpiment, is a yellow powder known as *king's yellow*. *Arsenic acid*, in the form of its potassium and sodium salts, which are white, crystalline and soluble in water, is used as a fly poison and in the manufacture of aniline dyes. Injurious effects, such as local skin eruptions, are sometimes caused by the action of the arsenical compound present in the dye of stockings, etc.

368 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

Arseniuretted hydrogen, or arsine, is a very poisonous gas. It is produced when hydrogen is generated in the presence of a compound of arsenic, for example, in the action of mineral acids on impure metals, as occurs in balloon filling, etc.

Salvarsan and the many similar derivatives of arsenobenzene, which are extensively used in the treatment of syphilis and other diseases, may give rise to fatal poisoning.

Sodium arsenite, in the form of solutions of arsenic in caustic soda, or in sodium carbonate, is commonly used for the preparation of fly-papers, weed-killer, preservative for wood, arsenical sprays for fruit trees, etc. Weed-killer and some of the so-called preservatives for wood contain as much as 20 per cent. to 40 per cent. of arsenic in solution, and are intensely poisonous. Both weed-killer and the arsenic obtained from fly-papers have been used for homicidal purposes.

Arsenic in food.—Accidental contamination of food with arsenic, or its preparations, such as weed-killer, has occurred. Arsenical pigments have been used for colouring sweets and cakes, with fatal result. A serious epidemic occurred in 1900, due to the contamination of commercial glucose by arsenic. Sulphuric acid prepared from pyrites and containing a considerable amount of arsenic had been used in the process of the conversion of starch into commercial glucose, so that the latter became impregnated with arsenic. The use of the glucose in the manufacture of beer led to the arsenical beer poisoning epidemic which occurred in Manchester and the North of England. A Royal Commission investigated the cause of this epidemic, and safeguarded the further occurrence of such poisoning. Limits of the amount of arsenic permitted in food-stuffs were fixed at $\frac{1}{160}$ gr. per gallon for liquids and per pound for solids.

The varieties of arsenical poisoning are—(1) acute, (2) chronic, (3) arseniuretted hydrogen poisoning, and (4) poisoning by salvarsan or arsenobenzol derivatives.

1. ACUTE ARSENICAL POISONING

Pathology.—The stomach contents usually contain much mucus, which may be blood-stained. The signs of gastro-intestinal inflammation will be present. The mucous membrane is swollen, red and congested, and petechiæ are usually well marked. The redness is most marked on the summits of the rugæ. When the arsenic has been taken in solid form, white or pigmented particles may be seen on the mucous membrane of the stomach. The duodenum shows marked redness and congestion, and petechiæ may be present; there is usually marked yellow staining, due to altered bile. The small intestine may show similar signs to the duodenum, but these diminish markedly on passing downwards. The liver, kidney and other organs may show cloudy swelling. In fatal cases the arsenic absorbed into the tissues has a preservative action, and tends to delay putrefaction.

Symptoms.—When the poison is taken by the mouth, if well diluted or mixed with food, no taste or pain in the mouth or throat is experienced. The symptoms commence within an hour if the stomach is empty; but may be delayed if the stomach is full, and if the poison is in the solid state there will be further delay. A burning pain occurs in the epigastric region, and nausea

and vomiting usually follow. The vomit will contain any food present in the stomach, and there is often much mucus. Bile is usually present, and sometimes streaks of blood. As the poison is passed on to the intestine, abdominal pain, of a griping or colicky type, and usually diarrhoea occur. The stools are watery, and may contain flakes of mucus. The continued vomiting and diarrhoea cause exhaustion, faintness and collapse. Cramps in the legs may occur, but are not a constant symptom. In a severe case restlessness, stupor and coma develop, and death follows shortly. Death in an acute case may occur within 24 hours, or may be delayed for 3 days or more. When several repeated doses are taken, so that the symptoms are protracted over several days, some of the symptoms of chronic arsenical poisoning may develop.

Fatal dose.—Two grains of arsenic have caused death in a woman, and this is accepted as a possible fatal dose.

Treatment.—The stomach should be washed out, and afterwards as an antidote freshly precipitated ferric hydrate may be given. This is prepared by adding to half a tumblerful of water half an ounce of tincture of perchloride of iron and also sodium carbonate solution till the mixture is distinctly alkaline. Pain is relieved by the hypodermic injection of morphine. Demulcent drinks should be given, and the usual stimulant treatment for collapse.

2. CHRONIC ARSENICAL POISONING

Symptoms.—The gastro-intestinal symptoms—nausea, abdominal pain, vomiting and diarrhoea—are not prominent, and even may be absent. The tongue is often covered with a silvery white fur. General malaise, anorexia and anaemia are usually present. Irritation of the throat and huskiness of the voice, due to the presence of pharyngitis and laryngitis, result. Conjunctivitis may occur, with redness and swelling of the eyelids. Skin affections, such as erythema, herpes, pigmentation, or erythromelalgia, are commonly to be noted.

If taken medicinally, or otherwise, over a long period, arsenic produces a marked general brownish pigmentation of the skin, with localised patches where the pigmentation is darker in colour. The appearance of the skin resembles that of Addison's disease, but differs from this condition in the absence of pigmentation of the mucous membrane and in the presence of the other signs of chronic arsenical poisoning and of arsenic in the urine and hair and nails. Thickening of the epidermis of the soles and palms, and irregular thickening of the nails are present in long-standing cases. In some cases salivation is a marked feature, a condition of paroxysmal attacks of excessive secretion of saliva occurring. Symptoms of multiple neuritis are likely to develop, and these affect both the upper and lower extremities.

Long-continued poisoning causes marked anaemia, peripheral neuritis, progressive wasting and heart weakness, death resulting from exhaustion and cardiac failure, ascites and general oedema occurring towards the end. The urine, faeces, the distal portions of the hair and the nails contain arsenic, its detection serving to confirm the diagnosis during life. The tests for arsenic will be found in works on toxicology. It must be remembered that in cases of suspected arsenical poisoning the diagnosis can always be made

370 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

with certainty by an analysis of the urine, vomit and fæces, and these should always be taken for examination, the tests being made by an expert toxicologist.

Treatment.—This consists in the prevention of the absorption of arsenic in any way, and eliminative and stimulant treatment.

3. ARSENIURETTED HYDROGEN POISONING

Arseniuretted hydrogen is a very powerful poison, and cases of poisoning result when hydrogen containing the gas is inhaled. Cases have also occurred when "ferro-silicon," a substance used for hardening steel, has come in contact with water, when a mixture of arseniuretted and phosphoretted hydrogen is evolved. Arseniuretted hydrogen has a very toxic action on the liver and kidneys, and it is also a blood poison.

Pathology.—Marked degenerative changes in the cells of the liver and kidneys, and numerous petechiæ on the mucous and serous membranes, are to be noted.

Symptoms.—Malaise, headache, dizziness and shivering occur within a few hours. Vomiting, jaundice, hæmaturia and anæmia develop. Delirium, stupor and coma precede death, the symptoms being exactly similar to those of icterus gravis.

4. POISONING BY SALVARSAN AND ARSENOBENZENE DERIVATIVES

Salvarsan and kharsivan are usually administered intravenously. After a full dose (0·6 gramme) usually nausea, a slight rise of temperature, with perhaps vomiting and a little diarrhœa, occur in the following 24 hours, after which the patient is quite well. Occasionally severe vomiting and diarrhœa, with furred tongue, erythematous rash and acute gastro-intestinal symptoms, may follow. In such cases it is probable that there has been some decomposition in the solution administered, the symptoms resembling those of acute arsenical poisoning. This type of poisoning is rare.

When dangerous toxic symptoms occur after salvarsan they are usually of the following type: After an interval of 2 or 3 days, vomiting and restlessness, delirium, stupor, often with twitchings of muscles, convulsions and Cheyne-Stokes breathing, occur. Sometimes jaundice may be observed. Coma develops, suppression of urine, and death may occur within 48 hours of the onset of symptoms. The symptoms are those of an auto-intoxication like icterus gravis, and are the result of the action of salvarsan causing impairment of the function of the liver and kidneys. The prognosis is very grave. Treatment consists in the administration of alkalis by the mouth and bowel, and saline per rectum.

Salvarsan and allied compounds often cause, especially after the administration of successive doses, such damage to the liver that extensive necrosis occurs and toxic jaundice develops, which may be fatal (see also p. 210).

CHRONIC MERCURIAL POISONING

Ætiology.—This condition occurs chiefly amongst workers in the metal, or amongst those who are constantly brought into contact with compounds of mercury; for example, it is found amongst those engaged in mining

and separation of the metal, *e.g.* at Almaden in Spain, at Idria in Austria, and at the mines in California, China, Peru and the Ural Mountains. Mirror makers, thermometer and barometer makers, and those engaged in the manufacture of chemical and electrical apparatus in which metallic mercury is used, are exposed to risk. Those engaged in the frequent handling or grinding of mercury compounds in chemical works and businesses are sometimes attacked. It must be remembered that mercury is volatile at ordinary temperatures, and those working in ill-ventilated rooms where mercury is exposed are liable to attack. Cases have been recorded of chronic mercurial poisoning from the amalgam in tooth stoppings, and from sojourn in a respiration apparatus fitted with mercury air-valves. The nitrate of mercury is used in the preparation of some furs, and hat makers and furriers may be liable to chronic poisoning. The condition may result from the medicinal use of mercury, as for example from the continued administration of calomel or blue pill or other mercurial preparation in small doses, or from the prolonged use of mercurial vaginal douches or skin applications.

Symptoms.—Dyspepsia, anæmia, general cachexia, with loss of weight and strength, occur. Sometimes a marked blue line is seen on the gums if the teeth are neglected. Stomatitis is one of the most constant symptoms; increased salivation and marked foetor of the breath occur, and are associated with tenderness of the gums, looseness of the teeth, and all the symptoms of severe pyorrhœa; this condition is associated with a streptococcal infection of the gums, and is progressive, so that after the patient is removed from the influence of mercury or its compounds a condition of pernicious anæmia may result. In 1920 the writer had under his care at St. Mary's Hospital a man suffering from typical pernicious anæmia. The patient had for some years been working at a chemical store where he frequently had to grind and handle vermilion (mercury sulphide). This set up a severe pyorrhœa, from which resulted the progressive pernicious anæmia, which continued long after his removal from the influence of mercury. A streptococcal infection was found in the gums, and a secondary intestinal infection resulted. Colitis, often of an ulcerative type, may result from chronic mercurial poisoning. It is a dangerous complication and difficult to treat. Skin rashes of an erythematous, eczematous or pustular type have occurred. Glycosuria has been described, but it is rare.

The most characteristic symptoms are the nervous manifestations. Tremors, affecting the muscles of the tongue and face, the arms and hands, and later the legs and trunk, occur. They are of a fine type, resembling paralysis agitans; but the rigidity of the muscles in the latter condition is absent, nor are the characteristic facial appearance and gait present. Sensory disturbances, such as anæsthesia or hyperæsthesia, may occur, and sometimes marked mental symptoms, such as hallucinations, delusions and mania result. The kidneys may be affected and a chronic nephritis develop.

Diagnosis.—This is made by the history and symptoms; but it should be confirmed by the analytical tests. Mercury is excreted in small amounts in the fæces. The greatest care should be taken that no mercurial preparation is being administered medicinally during any time when the patient is undergoing treatment. The fæces are collected, and the organic matter destroyed by treatment with hydrochloric acid and potassium chlorate. The resulting

372 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

solution is submitted to electrolysis, and the mercury present is deposited on a gold kathode, from which it may be dissolved and submitted to the usual chemical tests.

Treatment.—This consists in the removal from all influence of mercurial intoxication. Saline aperients, such as Epsom salts or sodium sulphate, should be given daily, to promote the free elimination of the poison by the bowel. The treatment is conducted on general lines to counteract the symptoms produced.

LEAD POISONING

ACUTE LEAD POISONING

This is rare. It usually results from swallowing a large dose of a soluble lead compound, such as acetate of lead, which is also known as sugar of lead, from its sweetish taste.

Pathology.—There are the usual signs of acute gastro-enteritis, and the stomach may be covered with a whitish grey deposit. The wall of the stomach and duodenum is sometimes thickened and softened, and erosions may occur from the local action of the lead compound.

Symptoms.—An astringent metallic taste is at once experienced, followed by a feeling of constriction in the oesophagus. A burning sensation and pain are felt in the epigastrium, and vomiting occurs. The vomit contains opaque whitish material, due to the precipitated albuminate of lead and lead chloride, formed by the action of the lead salt on the gastric contents. Blood may also be present. Severe colicky pains occur in the abdomen, with rigidity of the abdominal muscles. Pressure on the abdomen gives relief, and the patient may bend forwards for this purpose, or lie on his abdomen. The tongue is coated, and the bowels are usually constipated; but occasionally diarrhoea occurs. The stools are dark coloured, owing to the formation of black sulphide of lead. Prostration and collapse occur, if the abdominal symptoms are severe. There may be numbness or paræsthesia of the limbs and cramps in the legs. The urine may be partially suppressed. A blue line on the gums does not usually occur during the acute symptoms following a single dose of the poison.

The subacute form of poisoning follows the taking of repeated doses of a soluble lead compound. It may occur from repeated medicinal doses of lead acetate given to control diarrhoea. The symptoms of abdominal colic (lead colic) are pronounced, and the bowels are very constipated. The other symptoms of acute lead poisoning occur, but are less intense in character. A blue line usually appears round the margin of the gums, owing to the formation of lead sulphide by the action of the decomposing food material around the teeth on the albuminate of lead in the gum tissue. If the teeth are frequently cleaned a blue line on the gums is less likely to be formed. Symptoms of lead neuritis may result if the symptoms are of long duration.

Diagnosis.—The diagnosis of acute or subacute lead poisoning can be confirmed by analysis of the vomit and fæces for lead during life, and after death by finding lead in the gastro-intestinal tract, liver, spleen and kidneys.

Acute and subacute lead poisoning are rarely fatal.

Treatment.—If the case is seen within 3 hours of swallowing the poison, the stomach should be washed out with water. Sulphate of soda or sulphate of magnesia in half-ounce doses, dissolved in half a tumblerful of warm water, should be given every 4 hours, till free purgation results, and this may be assisted by soap enemata if necessary. The abdominal pain may be relieved by hot applications, or, if necessary, morphine and atropine hypodermically. Demulcent drinks, such as albumin water, barley water and milk, should be given, and saline aperients should be administered for some weeks.

LEAD TETRA ETHYL POISONING

Lead tetra ethyl is a liquid organic compound of lead, which is very poisonous. It has a selective action on the central nervous system, and produces acute mental symptoms, such as mania, and the symptoms of "lead encephalopathy." Several fatal cases have been recorded. This substance has attracted public notice recently, owing to its use as an addition to motor petrol, in amounts of about 1 in 1300. This variety of motor fuel is known as "ethyl petrol," and its use has been submitted to a Government inquiry. No cases of poisoning from the use of ethyl petrol have been recorded, but special care is required in its preparation and handling, for fear of toxic effects.

CHRONIC LEAD POISONING

Ætiology.—Chronic lead poisoning is common, and is caused by the continued absorption of lead into the system. In certain industrial occupations lead and its compounds are largely used, and workers are exposed to serious risks. The strict regulations of the Home Office have greatly reduced the frequency of lead poisoning in these industries; but there are numerous occupations, such as those of painters and plumbers, which cannot be efficiently controlled, and these give rise to a large number of cases of poisoning. The channel of absorption of lead appears to be the alimentary canal, and the poison is taken into the system, either in the form of small particles entering the mouth or nose, which are swallowed, or by eating of food, which becomes contaminated with lead compounds from the hands of the worker, owing to lack of cleanliness. Statistics show that women are more susceptible to lead poisoning, when exposed to the same risks as men. Idiosyncrasy is a factor in the development of lead poisoning, certain persons being more susceptible, especially those with gouty tendencies. Alcoholism also seems to be a predisposing cause.

The sources from which lead is derived in chronic poisoning are very numerous, and they may be divided into those due to occupation risks, and those due to accidental poisoning.

Occupation risks.—Workers in lead factories, especially white lead, are often attacked; but the frequency of occurrence amongst them has been much reduced by recent legislation. Painters provide the largest number of cases. Plumbers, earthenware makers who use lead glazes, file cutters, compositors who handle lead type, gasfitters who use red and white lead, and those working with electrical lead accumulators, are exposed to serious risks. The enamelling of iron plates with lead glazes and the smelting of lead ores also give rise to a certain number of cases.

Accidental causes.—Drinking water, especially if it is soft, or contains traces

374 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

of acids derived from peaty sources, may dissolve lead from lead pipes, or cisterns, and so give rise to poisoning. The cooking of food in vessels tinned with solder containing lead may give rise to lead poisoning, especially if vegetable acids are present. The lead glaze on earthenware vessels may contaminate food or drink containing organic acids, *e.g.* vinegar, lemon juice, cider and home-made wines. Tinned foods sometimes contain lead from solution of the solder used in the tinning process. The lead foil used for wrapping sweets or foods may give rise to contamination of the food. Beer or cider, drawn from casks through lead pipes for consumption, may become heavily contaminated. Hair dyes and cosmetics containing lead, and aerated waters in syphons with pewter or lead valves, and chromate of lead, which has sometimes been used to colour confectionery and for dyeing hosiery, may all give rise to lead poisoning. Accidental poisoning may occur in many other ways than those mentioned.

Abortifacient uses of lead.—It has been well known that lead compounds, if absorbed into the system, give rise to abortion in pregnant women. A like effect has been observed in animals in the proximity of lead works. Lead plaster, known as “diachylon,” has been largely used in certain districts by pregnant women in order to cause miscarriage, the substance being swallowed in small portions rolled up in the form of a pill. This form of lead poisoning is very dangerous, and usually if a miscarriage occurs death occurs later from lead poisoning. In consequence of this custom, the sale of lead plaster or “diachylon” has been restricted by placing it in Part I. of the Poisons Schedule.

Pathology.—Arterial disease and chronic interstitial nephritis result from chronic lead poisoning, and are the common causes of death, so that the usual post-mortem signs of these conditions are generally found. Lead paralysis is usually regarded as peripheral; but it does not correspond with the distribution of the peripheral nerve supply. Degenerative changes have been found in the anterior cornual ganglion cells and in the peripheral nerves.

Toxicological analysis will show a wide distribution of lead in the various organs; but since death frequently occurs years after exposure to lead poisoning, the quantities found may be very small, and require special methods for their detection. Recent researches by refined methods of analysis have shown that lead is commonly present in the urine of persons in normal health. Quantitative analysis is, therefore, necessary before deciding that lead poisoning is present. The amounts found should far exceed those minute quantities that may be present normally.

Symptoms.—The most important changes caused by chronic lead poisoning are those of chronic interstitial nephritis and arterial disease, and many of the symptoms, for example, cachexia, chronic dyspepsia, anæmia, vertigo, high blood-pressure and cerebral symptoms, are really due to these secondary conditions rather than to the direct action of the lead in the system. The early symptoms are dyspeptic in type: anorexia, constipation, epigastric and abdominal pains, and discomfort bearing an indefinite relation to food. The skin is of a lemon colour. Anæmia of a secondary type occurs, and may be marked. Vertigo, headache and insomnia often occur.

Special symptoms due to lead.—The blue line on the gums has already been described. Colic usually occurs as an early symptom, but it may be absent in cases showing marked arterial disease and renal changes. Arth-

ralgic pains round various joints are common, the knees, shoulders and elbows being most frequently affected, and creaking or grating and impairment of movement may be present. Gouty changes of an advanced type are seen, especially in the fingers in chronic cases. Nervous.—Lead neuritis is the commonest manifestation. This is usually motor in type, and few, if any, sensory changes occur. The neuritis is generally bilateral, but may be limited to one side. The upper extremities are generally only involved, and the extensors of the forearms are most commonly affected. The extensors of the fingers and wrist are usually the first to suffer, the supinator longus being spared, so that marked wrist-drop occurs early. Exceptionally, an upper arm paralysis results, the deltoid, biceps, coraco-brachialis and supinator longus being attacked. Sometimes the interossei and thumb muscles are affected, and a "claw hand" results. The lower extremities may be affected, but only after marked changes in the upper extremities, and the extensor muscles of the feet are usually involved in such cases.

The cerebral symptoms have been termed "Lead encephalopathy." Headache, vertigo and insomnia are common. Amaurosis may occur, and sometimes marked mental symptoms, such as hallucinations, delusions and delirium, are present. Drowsiness and stupor may occur and develop into coma. Epileptiform convulsions are common symptoms in diachylon poisoning, and they may occur as the result of the uræmia from the nephritis caused by the poison. Papilloedema occurs in chronic lead poisoning.

Any of the symptoms of chronic interstitial nephritis or arterial disease, such as those due to uræmia or cerebral hæmorrhage, may occur as late symptoms of chronic lead poisoning.

Prognosis.—Chronic lead poisoning usually attracts attention in consequence of the symptoms due to the arterial disease and chronic renal disease caused thereby. In such cases the prognosis is grave, and is determined by the arterial and renal damage which has resulted. The occurrence of convulsions is of grave significance. Symptoms of chronic lead poisoning, such as Lead colic, or neuritis, if not associated with arterial or renal changes, are not of grave significance, and will most likely clear up, though some permanent wasting may occur in cases where neuritis is present.

Treatment.—Prophylaxis is all-important, and should early symptoms of lead poisoning occur, permanent removal from any chances of lead absorption is imperative. Cleanliness of the hands, and prevention of access of lead, or its compounds, to the mouth, or nose, by avoidance of contaminated dust, and the use of respirators are essential. Saline aperients, such as sulphate of soda or sulphate of magnesia, should be taken daily over a long period to eliminate the lead from the system. Iodide of potassium in doses of 10 grains three times daily may be taken for a long period, if tolerated. The symptoms of secondary anæmia, arterial disease, and chronic interstitial nephritis, should they occur, require treatment on the lines indicated under these headings. Lead neuritis should be treated on the lines described under peripheral neuritis.

CARBON MONOXIDE POISONING

Carbon Monoxide, or Carbon Oxide (CO), is a very poisonous gas. If present in the air breathed in an amount equal to 0.2 per cent. it is capable

of destroying life ; while an atmosphere containing 0.05 per cent. of carbon monoxide gives rise to definite symptoms of poisoning.

Ætiology and Pathology.—When carbon is burnt in a limited supply of oxygen, carbon monoxide is produced in varying amount. Thus, charcoal fires and braziers give rise to considerable amounts of CO. *Gas geysers*: Certain types of water heaters and slow combustion stoves are common sources of production of the gas, which may give rise to poisoning if the ventilating flues are inadequate. In lime kilns there is evolution of CO₂ and CO. The exhaust fumes from motor-cars and petrol-burning engines contain approximately 6 per cent. of carbon monoxide. The commonest source of carbon monoxide poisoning is from coal gas which is used for illuminating or heating purposes. Coal gas contains normally a percentage of from 4 to 10 per cent. carbon monoxide, and it often approximates to the latter figure. It, either from accidental leakage of pipes or from purposive exposure due to turned-on taps, is a common cause of death. Carbon monoxide occurs in the smoke and fumes from fires with inadequate chimney ventilation. It is important to remember that the products of combustion of gas stoves and gas fires contain an appreciable amount of carbon monoxide. The flues from these are often quite inadequate completely to carry away the products of combustion, in which case the gas stoves and gas fires, when used, give rise to the addition of carbon monoxide to the air of dwellings and so are a source of ill-health or chronic CO poisoning. *Industrial poisoning*: This occurs from the fumes from blast furnaces, in iron smelting, and in blasting operations in mines. In coal mines the explosions from coal dust, or inflammable gases, lead to the production of carbon monoxide ("after-damp"). *Water gas* is prepared by passing steam over red-hot coke, and contains upwards of 30 per cent. CO. It is used for heating purposes, and is sometimes added to coal gas before its distribution. It is very poisonous and, owing to its slight smell, is very dangerous unless mixed with odorous gases. *Producer gas* is prepared by passing a mixture of steam and air over red-hot coke in retorts. It is used for heating the coal retorts for the preparation of coal gas. Producer gas is a mixture of carbon monoxide, hydrogen and nitrogen, and is similar in composition and properties to water gas, and may contain as much as 30 per cent. of carbon monoxide. Industrial dangers also arise from leakages in the plant and from the process of charging the producer-gas retorts.

Action of carbon monoxide.—Carbon monoxide has 220 times the affinity for the blood pigment of the red blood corpuscles (hæmoglobin) that oxygen has. If respired, it will, therefore, more or less completely displace the oxygen from its combination with the hæmoglobin of the red blood corpuscles. This prevents oxygen being carried in requisite amount by the blood corpuscles to the tissues of the body, which thus become deprived of the oxygen necessary for their vital functions. The extent to which the hæmoglobin is saturated with carbon monoxide depends upon the percentage of the latter in the air breathed. When the hæmoglobin becomes one-third saturated with carbon monoxide, definite symptoms of poisoning occur, and when the saturation percentage exceeds 50 per cent. there is grave danger of a fatal issue. It is important to note that carbon monoxide is a tissue poison. It does not act simply as an oxygen depriver to the tissues, but undoubtedly has in addition a narcotic action upon them. This is best

illustrated by considering the serious symptoms of narcosis (muscular paralysis and loss of consciousness) which occur in a person in whom 50 per cent. saturation of the hæmoglobin with carbon monoxide exists. These symptoms far exceed in gravity those of a person possessing only 50 per cent. of hæmoglobin as the result of anæmia from disease or loss of blood (hæmorrhage). Carbon monoxide acts as a tissue poison especially to the nervous system, but there is evidence to show that it acts on all the tissues of the body, notably the cardiac muscle, and may cause degenerative changes in them.

Post-mortem appearances.—The external appearances are characteristic, the cheeks and lips and post-mortem stains appearing cherry-pink in colour. On opening the body, the blood, muscles and internal organs have a characteristic cherry-pink colour. The lungs may show areas of consolidation due to broncho-pneumonia. Small hæmorrhages may be visible, and œdema is common. The brain shows congestion and œdema, and small punctiform hæmorrhages may be found in the cortex and basal ganglia. The heart may show degeneration of the cardiac muscle and punctiform hæmorrhages beneath the pericardium. In some cases of carbon monoxide poisoning putrefaction is markedly delayed.

Symptoms.—The onset of carbon monoxide poisoning is usually very insidious, since the gas is odourless and any smell of an atmosphere containing it is due to the presence of other gases or vapours having a characteristic odour, and also the gas may be respired freely without any irritation to the air passages. Premonitory symptoms are giddiness, a swimming sensation, headache or a sensation of heaviness or constriction in the head, noises in the ears, and a feeling of oppression in the chest. Sometimes nausea and vomiting occur. The onset is, however, often sudden, and this is likely to be so when the percentage of carbon monoxide is relatively high. In these cases, the first symptoms may be sudden collapse, with loss of consciousness, and this is associated with complete loss of power of the muscular system.

Cardio-vascular symptoms, such as violent beating of the heart and throbbing of the blood vessels, occur. The blood-pressure rises at first, and the pulse is full and may not be increased in frequency. Muscular weakness and drowsiness quickly supervene in severe cases, and the patient falls down unconscious. In the *condition of coma* the blood-pressure falls and the pulse becomes rapid and small. The conjunctivæ become markedly hyperæmic and the eyes have a staring appearance, the pupils being partially dilated, and do not react to light. The complexion has a cherry-red appearance. Froth may be present on the lips. The breathing is stertorous. The temperature is usually lowered in the early stages of coma, but is sometimes raised above the normal in the later stages. There is relaxation of the sphincters in severe cases. Broncho-pneumonia may develop if the coma is prolonged for more than a few hours. When the state of coma lasts only for an hour or two, the recovery may be rapid. It is very important to remember that though the muscular power recovers quickly, the tissues of the body have been submitted to a serious acute toxæmia. In all cases where coma has occurred, careful after-treatment is essential, since thereby the occurrence of after-effects, such as cardiac weakness, nervous symptoms, such as weakness or paralysis, or mental disorder, may be avoided.

378 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

Diagnosis.—In all cases, at the earliest opportunity after the immediate treatment has been commenced, it is desirable that some blood be removed from a vein for analysis. About 10 c.c. should be removed from a convenient vein of the arm, and placed in a small test-tube so as almost to fill it, and a cork inserted. This can then be sent to the laboratory for analysis. It should not be shaken or exposed to the air. The carbon monoxide present in the blood is most conveniently estimated by means of Hartridge's reversion spectroscope. The percentage of carbon monoxide present is of value not only for diagnosis but for prognosis.

It may be remarked that a record of the blood analysis in cases of carbon monoxide poisoning would be of great interest and value for research purposes.

Treatment.—Elimination of the carbon monoxide from the system is best effected by the ventilation of the lungs with pure air and oxygen.

Immediate removal of the patient to a pure atmosphere is the first step. Onlookers should not be allowed near the patient. If removed to a room, the windows and doors should be widely open and a free current of air encouraged. Complete rest is absolutely necessary, and attempts to keep the patient on the move should be forbidden. The patient should be lying flat, and all constricting clothing round the neck and chest should be loosened or removed. Care should be taken that the air passages are free, and any froth or saliva wiped away from the mouth or nose. If necessary, the tongue should be pulled forwards with tongue forceps. In some cases, especially if convulsions have occurred, a gag may be required to keep the mouth open. Warmth of the body is important, and blankets and hot-water bottles should be used.

Artificial respiration is of great value, as this enables the air and oxygen to reach the alveoli of the lung. The method most suitable is Sylvester's, for this permits of free access of fresh air to the air passages and is more convenient for the administration of oxygen. The upper extremities are moved upwards to a fully extended position above the head and kept on the stretch for two seconds, they are then lowered to the sides of the chest and firmly pressed against the ribs for about two seconds, the double movements being repeated about fifteen times per minute. Oxygen should be administered without delay, and for its efficient administration an oxygen cylinder, with a suitable regulating valve tap, a rubber bag and Haldane mouthpiece are required. Recent researches have shown that the administration of oxygen mixed with about 5 per cent. of carbon dioxide acts as a powerful stimulant to the respiratory centre, and causes deep and rapid breathing. It has been calculated that this mixture increases the lung ventilation by about five times. The use of the mixture in severe cases of carbon monoxide poisoning is of great value, since it enables a much greater amount of oxygen to reach the lung alveoli. Its use, however, should be reserved for the severe cases of poisoning. The mixture of oxygen and carbon dioxide can be used in two ways: (1) By using a sparklet bulb. A special metal perforator with tube attached is available for the purpose of perforating the sparklet and admitting the carbon dioxide at a desired rate by means of a rubber tube. The rubber tube is placed under the oxygen mouthpiece, so that the mixture of oxygen and carbon dioxide can be conveniently administered. This method of administration is easily and con-

veniently effected and is entirely free from any risk. (2) Gas cylinders, which contain a mixture of oxygen with 5 per cent. carbon dioxide, are on the market. This mixture has been used as a respiratory stimulant during anæsthesia. When the respiration of the patient has become normal, pure oxygen should be administered for about 3 hours, with short intervals for feeding. This will be of value in getting rid of the carbon monoxide from the blood of the patient.

For cardiac stimulation.—Strychnine, gr. $\frac{1}{30}$. Camphor, grs. 3, in oil and ether. Pituitary extract, 1 c.c., may be given hypodermically. Adrenalin hydrochloride solution, 1:1000, 5 to 10 mins. *For respiratory stimulation.*—Atropine sulphate, gr. $\frac{1}{100}$, may be given hypodermically, and repeated, if required. Lobeline, gr. $\frac{3}{20}$, hypodermically, has recently been used with benefit, and may be tried with advantage. It is supplied in solution in ampoules. The dose may be repeated at intervals until the respiration becomes normal. *Collapse* in severe cases may be treated by means of subcutaneous normal saline (1 pint), or possibly blood transfusion (1 pint).

After-Treatment.—In mild cases, where coma only lasts a very short time, it is important that the patient should be kept completely at rest in bed and under medical supervision for a few days. In severe cases, where coma has been prolonged for several hours, complete rest in bed under medical supervision for 2 or 3 weeks or more will be required, since otherwise there is a danger of after-complications.

W. H. WILLCOX.

LACQUER POISONING

Definition.—A form of poisoning met with amongst people who handle lacquer (*Rhus vernicifera*).

Ætiology.—It is met with in China and Japan, the home of the lacquer industry. Raw lacquer and its derivatives are the most dangerous.

Symptoms.—Fever, itching and a feeling of tension of the skin of the head, face and limbs, with, later, œdema of the affected parts, are the initial symptoms. Catarrh of the nose may occur. Red papules finally appear on the œdematous areas, and form blebs full of serum and pus. These eruptions are found on the arms up to the elbows, and on the legs as far as the knees. The pustules may become confluent, and on bursting form large ulcers.

Diagnosis.—The occupation of the patient gives the clue.

Prognosis.—This is favourable; death is said not to occur.

Treatment.—Care should be taken in handling the lacquer; some people are much more susceptible than others. Washing with soap and brisk scrubbing should be adopted to get rid of as much of the poison as possible. Antiseptics to the eruption, lead lotion and astringents such as tannin are all recommended. The juice of the garlic, applied externally, is said by the Japanese to be an antidote.

G. CARMICHAEL LOW.

POISONS ACTING ON THE LIVER

The liver plays a most important part in the body metabolism, and impairment of its metabolic functions quickly leads to toxic symptoms.

Thus, *protein metabolism* is mainly carried out in the liver, and if this function is impaired by the action of toxic substances on the liver cell, nitrogenous compounds intermediate between protein and urea are formed, which have a profound toxic action on the body. Thus, many poisons by their direct action on the liver cell cause such impairment of the controlling influence of the liver on protein metabolism that symptoms of auto-intoxication result. These symptoms may be of the gravest kind and constitute the condition known as *icterus gravis*, which is the clinical manifestation of an extensive pathological damage to the cells of the liver.

If the process is rapid the morbid anatomical condition found post mortem will be a large yellowish liver of fatty appearance, and on microscopical examination the liver cells will be found to show extreme degeneration and to be often distended with fat. The swelling of the liver cells may lead to obstruction in the passage of bile through the small intrahepatic bile vessels, so that the liver becomes stained with bile and a general jaundice of the body may result. This condition is seen in cases of acute liver poisoning, such as that resulting from phosphorus, arsenobenzene compounds and chloroform after an anæsthetic, and it is sometimes seen in cases of alcoholic poisoning.

Where the process is less rapid, the liver cells after undergoing degeneration, shrink up and disappear, so that a condition of acute yellow atrophy results. The morbid appearances of the liver in this condition are described later (see pp. 626-7). The morbid anatomical condition of acute yellow atrophy of the liver may result from many liver poisons, for example: tetrachloride of ethane, trinitrotoluene; and—where the patient survives for several days—it is found in poisoning by phosphorus, arsenobenzene compounds, chloroform, etc. The condition of acute yellow atrophy of the liver usually causes obstruction of the intrahepatic bile vessels, and is thus associated with general jaundice. Acute yellow atrophy of the liver causes complete impairment of the protein metabolic function of the liver, so that the clinical symptoms of auto-intoxication, namely, *icterus gravis*, result.

In some cases of liver poisoning where a portion only of the hepatic cells are destroyed by the degenerative processes, the affected cells shrink up and disappear, their place being taken by connective tissue, so that a condition of "replacement fibrosis" of the liver results. This has been observed in tetrachlorethane poisoning, and may occur after trinitrotoluene, arsenobenzene, and any of the liver poisons where the process is not acute. The occurrence of "replacement fibrosis" in cases of acute liver poisoning has an important bearing on the pathology of cirrhosis of the liver. There appears to be little doubt that the production of various forms of cirrhosis of the liver is due to the action of poisons of different kinds on the hepatic cells, leading to their degeneration and disappearance, their place being taken by fibrous tissue.

The fat metabolism function of the liver.—Normally fat is stored up in the liver, being converted into salts of unsaturated fatty acids, and it is disposed of as required. Where the function of the hepatic cells is impaired, as occurs from the action of many of the liver poisons, such as phosphorus, arsenobenzene, and chloroform, the hepatic cells become engorged with fats of the saturated fatty acids, and the disposal of this stored fat cannot be effected, so that post mortem in acute cases a large canary-yellow fatty liver is found, the cells being distended with fat of a low iodine value.

The bile-producing function of the liver.—The action of poisons on the liver has a very important relation to the production of jaundice. Many liver poisons have a direct action on the intrahepatic bile vessels, causing an inflammatory catarrh, and an altered condition of the bile, which becomes viscid and irritant in its action. The classical example of this is toluylene-diamine, which was shown by William Hunter to cause a catarrhal inflammation of the intrahepatic bile-ducts in dogs, and this led to the rapid development of jaundice. The jaundice caused by many liver poisons, *e.g.* tetrachlorethane, trinitrotoluene, phosphorus, and arseniuretted hydrogen, is partly due to this cause, and the type of jaundice is known as hæmo-hepatogenous jaundice.

Many of the liver poisons causing hæmo-hepatogenous jaundice are also hæmolytic poisons, causing increased destruction of the red blood corpuscles; this is the case with toluylene-diamine, phosphorus and arseniuretted hydrogen, and many other poisons, so that an additional factor in the causation of hæmo-hepatogenous jaundice is an increased production of bile, consequent on the hæmolytic action of the poison. It is now held that "catarrhal jaundice," which has been thought to be due to an obstruction of the common bile duct from catarrh, is almost always intrahepatic in origin, the obstruction occurring in the small intrahepatic bile ducts from a catarrhal inflammation set up by some poison.

The function of the liver in protection of the body from poison.—In the case of poisons absorbed by the alimentary tract, the liver is the first line of defence, and much of the poison is taken up by it. In the case of poisons in the general circulation, as, for example, after the intravenous administration of arsenobenzene derivatives, the liver absorbs much of the poison from the blood stream. In its attempt to protect the body from the action of poisons, the liver is often severely damaged, many of its cells undergoing degeneration and necrosis. In consequence of the function of the liver in absorbing poisons from the portal or systemic circulation in cases of death from poisoning, the liver is the most important organ to be reserved for toxicological analysis. This function of the liver is the "toxiphylactic function."

Liver poisons may be classified into—(1) Chemical poisons; (2) bacterial poisons, resulting from bacterial infections, such as typhoid and paratyphoid fevers, streptococcal infections, influenza, and pneumococcal infections; (3) protozoal poisons, *e.g.* those of malaria, amœbic dysentery, relapsing fever, spirochætal jaundice, kala-azar, and yellow fever, all of which may be associated with degenerative changes in the liver, hepatitis and jaundice; (4) auto-intoxications, such as those occurring in the recurrent vomiting of children, and in the pernicious vomiting of pregnancy; (5) the poisons associated with blood diseases, such as pernicious anæmia, splenic anæmia, and acholuric jaundice.

It is only the chemical poisons with which we are here concerned. A great increase of our knowledge of these resulted from the use of poisons either industrially for war purposes or for the preparation of explosive munitions. The action of chemical liver poisons is usually twofold:—(1) The poison may have a poisonous action on the body apart from its effect on the liver, so that gastro-intestinal symptoms, skin rashes, etc., may occur. (2) The poison has a toxic action on the liver, and, if this is sufficiently severe, symptoms of auto-intoxication (icterus gravis), due to suppression of liver function, result

which are usually fatal. The symptoms of *icterus gravis* are mental irritability, vomiting, twitchings of muscles and stupor, developing into coma, and often associated with Cheyne-Stokes breathing and convulsions. Death usually occurs within three days. Jaundice, which may be only slight or deep, usually occurs; it may be present before the onset of the symptoms, or it may develop during their course, or in rare cases may be absent. Hemorrhages, e.g. hæmatemesis, melæna, hæmaturia or purpura, may occur during the course of *icterus gravis*. Not uncommonly the temperature rises to 102° F. or more shortly before death, and a temperature of 106° F. may occur.

Phosphorus is a classical example of a liver poison. If swallowed it acts as a gastro-intestinal irritant, and after 2 or 3 days, when the irritant symptoms may have subsided, the signs of the poison on the liver become manifest by hepatic enlargement, jaundice and fatal symptoms of *auto-intoxication* (*icterus gravis*).

Tetrachlorethane was used largely in the manufacture of aeroplanes as a constituent of the varnish applied to the canvas wings. The vapour of this liquid acted as a liver poison, causing toxic jaundice in the severe cases, and the terminal symptoms were those of "*icterus gravis*."

Trinitrotoluene, a yellow solid substance, used for its explosive properties in the manufacture of munitions. It caused skin eruptions, symptoms of gastritis and sometimes severe anæmia. Its effect on the liver was the production of toxic jaundice, and in the severe cases symptoms of *icterus gravis* were the terminal event.

Dinitrobenzene, *dinitrophenol* and *picric acid* are yellow powders used for explosive purposes, and they may cause anæmia, from blood destruction, and sometimes dermatitis. They are liver poisons, and have caused toxic jaundice, followed by fatal symptoms of *icterus gravis*.

Arsenobenzene derivatives.—These are usually given intravenously, and slight symptoms of gastro-intestinal irritation, etc., frequently follow their administration. A toxic action on the liver occurs occasionally in some cases, and after 3 or 4 days symptoms of profound toxæmia, *icterus gravis*, may result, and death may occur within 3 days of their onset. In some cases where the toxic action is less intense symptoms of toxic jaundice result. These may occur weeks or months after a course of salvarsan or its substitutes, and are associated with enlargement and tenderness of the liver and marked jaundice. The patient may recover, the liver shrinking and a condition of replacement fibrosis occurs. Where there is extensive liver degeneration, fatal symptoms of *icterus gravis* may develop. Cases of toxic jaundice from arsenobenzene derivatives are of common occurrence at the present time, and in all cases of jaundice inquiry should be made as to the previous administration of arsenobenzene derivatives.

Chloroform.—"Delayed chloroform poisoning" sometimes occurs 2 or 3 days after the administration of chloroform as an anæsthetic. The symptoms are those of *icterus gravis*, and may be fatal within 3 days of their onset. These cases usually occur in children, and are often associated with acidosis. As a prophylactic measure, plenty of sugar and carbohydrate food should be given to children up to the time that food has to be withheld, and if acetone or diacetic acid is present in the urine the administration of the anæsthetic should be delayed, if possible, until these substances disappear. If this is not possible, chloroform should not be given.

Arseniuretted hydrogen and phosphoretted hydrogen are both powerful gaseous liver poisons, and they also cause great blood destruction. They may cause death by the development of symptoms of *icterus gravis*.

Alcohol.—In certain cases of alcoholic poisoning great fatty enlargement of the liver occurs, and death results from symptoms of *icterus gravis*. In such cases the liver is canary-yellow in colour, fatty and much enlarged. The cirrhosis of the liver resulting from alcohol is probably a replacement fibrosis, following on the degenerative effect of the poison on the liver cells.

Mushroom poisoning.—Poisonous fungi eaten in mistake for edible mushrooms are powerful liver poisons. They usually cause acute gastro-intestinal symptoms, and in severe cases these may be followed by symptoms of acute auto-intoxication due to suppression of liver function, consequent on the intense degeneration of the hepatic cells.

W. H. WILLCOX.

FOOD POISONING

Food poisoning occurs when, in mistake for a wholesome food, some article is eaten which is of itself normally poisonous, or, owing to the food being rendered poisonous, by contamination from outside sources. The former is called *Endogenous Food Poisoning*, while the latter, which is the ordinary form of food poisoning, is spoken of as *Exogenous*.

ENDOGENOUS FOOD POISONING.—The following are examples:

(1) *Poisonous fungi* are sometimes eaten in mistake for edible mushrooms, and dangerous or even fatal results may follow, owing to the presence in them of poisonous substances. Thus, the fly fungus, *Amanita muscaria*, contains the highly poisonous alkaloid muscarine; another poisonous fungus, *Amanita phalloides*, contains a powerful toxic substance, phallin or amanita toxin, as its active principle; while *Helvella esculenta* is a fungus which owes its toxic properties to helvellic acid.

The immediate symptoms caused by poisonous fungi are those of acute gastro-enteritis, together with collapse from the effect of the poison on the nerve centres. Usually the liver suffers severely (see above). Death from auto-intoxication may occur after a few days, owing to cessation of function of the liver, and possibly also of the kidneys.

(2) *Poisonous fish*.—Certain fish, such as those of the species tetrodon, found in Japanese waters, are normally poisonous, and the same applies to mussels when grown under unhealthy conditions. The symptoms caused by these poisonous foods are those of acute gastro-enteritis, with marked nervous disturbance and collapse.

(3) *Poisonous parts of plants* may be eaten in mistake for foods; for example, aconite root for horse radish, or deadly nightshade berries for edible fruit.

POTATO POISONING.—Under certain conditions potatoes may contain a dangerous amount of the poisonous alkaloid solanine. This is produced by the growth of certain forms of bacteria in the tubers, which is likely to occur if, owing to improper storage, sprouting of the potatoes has taken place. The symptoms of solanine poisoning are those of acute gastro-enteritis, associated with nervous prostration and collapse, resembling those caused by poisonous fungi.

384 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

The above types of poisoning do not, strictly speaking, come under the term "Food Poisoning," because the offending articles are unwholesome or poisonous substances taken in mistake for wholesome foods; but in some countries certain harmful vegetables are more or less habitually used as foods. [See (4) and (5).]

W. H. WILLCOX.

(4) LATHYRISM.—

Definition.—A disease of certain countries, characterised by spastic spinal paralysis, and caused by poisoning with various kinds of chick pea or common pulse, *Lathyrus sativus*.

Ætiology.—The disease has been reported from India, Algiers, France and Persia. It used also to be met with in Italy. It is solely confined to countries where the pulse is used for food. Young people are specially liable to the complaint, and men much more so than women, probably because they are more exposed to the weather. Lathyrism is an intoxication produced by eating different kinds of chick pea, the disease occurring in epidemics amongst the poorest classes, who have fed for months on bread made from a mixture of pea and wheat flour. It is also eaten as porridge, or the peas are boiled with oil and then consumed.

Pathology.—Changes are found in the spinal cord, and consist of a slow sclerosis apparently of the lateral columns. If the lumbar enlargement is involved, incontinence of urine and fæces may be met with.

Symptoms.—The onset is often sudden, without premonitory signs. After a hard day's work in the rain a patient may wake next morning with stiff, weak and trembling legs, and very heavy to lift. These symptoms increase rapidly, and, in 10 days or so, walking, without the aid of a stick, is impossible. Both legs are usually affected simultaneously, first the calves, then the thighs. After having lasted for some time, a peculiar gait appears, and walking is only carried out by the aid of a two-handed staff. "The leg bearing the weight of the body is bent at the knee and trembles, while the advancing leg, dragged wearily forward, strongly adducted, is planted unsteadily directly in front of its fellow, the toes reaching the ground first." If the patient lies on his back, the spasm of the adductors ceases, and the thighs can be separated; there is no atrophy or loss of tone of the muscles, and no reaction of degeneration. The knee-jerks are increased, and ankle clonus is marked. Sensation is normal.

Diagnosis.—The occurrence of many cases at one time, and the history of chick peas being used as food, are sufficient to draw one's attention to the real nature of the cases.

Prognosis.—The patient does not die of the disease, but on the other hand rarely completely recovers, a certain degree of spasticity remaining.

Treatment.—Lathyrus must not be allowed to be used as a human food. Its abolition at once stamps out the disease. Avoidance of damp and wet ameliorates the symptoms. Massage and electricity are indicated.

(5) ATRIPLICISM.—

Definition.—A disease associated with local cedemas, disturbances of sensibility, and vaso-motor and trophic disorders.

Ætiology.—It occurs in North China. Females are oftener attacked than males; no age is exempt. The condition is due to poisoning with *Atriplex*

littoralis (Chenopodiaceæ). Poor people and beggars eat the young shoots, either raw in salads, or in bread.

Pathology.—There are no records of post-mortem examinations with proper histological examinations.

Symptoms.—The onset is sudden, occurring quickly after the ingestion of the plant. First, there is tingling of the fingers, then the backs of the fingers and hands begin to swell, then the forearms to the elbows, and finally the face with violent itching. There may be anæsthesia of the forefingers and thumbs. Heat sensation is increased. Scratching may cause an ecchymotic condition of some of the areas, from which eventually the skin is shed in patches, and ulcers may follow.

Diagnosis.—It may be mistaken for Raynaud's disease or erythromelalgia.

Prognosis.—The swellings last for a week or so and the general health is not affected. The ulcers often become chronic.

Treatment.—All that is required is to avoid eating the plant. Salines, gastro-intestinal disinfectants and, later, tonics may be employed.

G. CARMICHAEL LOW.

EXOGENOUS FOOD POISONING.—The contamination may be due to bacteria, or to fungi, or to chemical substances.

A. Contamination by Bacteria.

(1) The commonest type of "food poisoning" is that frequently known as "ptomaine poisoning," and is caused by contamination with the special bacteria associated with the condition; for convenience it is called "Bacterial food poisoning" (see p. 386).

(2) Specific diseases may be caused by the accidental contamination of food with the specific pathogenic organisms. Thus typhoid or paratyphoid fevers may be caused by milk or oysters containing the specific bacilli; scarlet fever or diphtheria by infection of milk with the specific virus; cholera by the contamination of foods or water with cholera germs, amœbic dysentery by contamination with the specific amœbæ or their cysts, and bacillary dysentery by infection of food with its specific bacilli.

A very common cause of these forms of food poisoning is the handling of food by persons known as "carriers," who are apparently healthy but harbour in their bodies the specific germs of a particular disease, their excreta containing large numbers of the pathogenic organism, so that it is an easy matter for the infection of a food-borne disease to be conveyed by the hands of a "carrier" who is engaged in any way in the handling of food; cooks or milkmen frequently spread infection in this manner. The course of the disease is exactly similar to that described under the diseases in question.

(3) Diseases in animals communicable to man may arise from the consumption of food derived from a diseased animal. Thus the flesh of an animal which has died from anthrax may give rise to this disease in man. Tuberculosis of the mammary glands in the cow will cause the presence of tubercle bacilli in milk, the consumption of which may give rise to human tuberculosis. The flesh of animals suffering from actinomycosis may cause this disease in man. Parasitic diseases, such as trichinosis and tapeworm infections, arise from the consumption of the flesh of animals suffering from

these infections. These types of food poisoning are fully described under the diseases in question.

(4) Specific organisms may produce in food highly poisonous toxins, the ingestion of which causes acute and perhaps fatal illness. An instance of this is Botulism (see p. 395).

B. Contamination by Fungi.

(1) ERGOTISM.—The grains of cereals attacked by the ergot fungus (*Claviceps purpurea*) are poisonous, and if consumed give rise to a series of symptoms known as ergotism. Two types of this condition are known—(a) The gangrenous type, where gangrene of the toes or fingers, and occasionally of the ears or end of the nose, occurs. (b) The nervous type, where sclerosis of the posterior columns of the spinal cord, or degenerative changes in the nerve cells of the brain result, causing characteristic nervous symptoms.

C. Contamination by Chemical Substances.

Chemical poisons may accidentally contaminate foods and give rise to the special symptoms of that kind of poisoning. Examples of this are :

Metallic poisoning resulting from contamination of tinned foods by poisonous metals derived from the container. This is a rare form of poisoning, and is only likely to occur when the contents of the tin are liquid, such as fruit juice, liquefied jelly or soups. If the tin is sound, and composed of pure tin, care being taken in the canning and in the soldering process, so that the solder does not come in contact with the contents of the tin, the risk of poisoning is negligible. Cases of poisoning have occasionally occurred from the solution of tin by the acid juice of tinned fruits, or by the solution of lead, derived from the solder, coming in contact with the tin contents. The symptoms of metallic poisoning are described elsewhere.

Arsenical poisoning from the contamination of commercial glucose during its manufacture is described under arsenical poisoning.

Drinking water may be contaminated by lead or copper, and give rise to chronic poisoning.

Food preservatives, such as boracic acid, formalin, and salicylic acid, if added to foods, may give rise to illness from their toxic effects. The addition of food preservatives to milk is for this reason prohibited by law in this country.

BACTERIAL FOOD POISONING

Synonym.—Ptomaine Poisoning.

This is the form of poisoning caused by the contamination of food with certain forms of bacteria, and the resulting symptoms are caused by the toxic substances produced in the food by its bacterial contamination, and there may also be an actual bacterial infection, should the organisms not be killed in the process of cooking. Since bacterial contamination finds a most suitable culture medium in foods rich in protein, this type of food poisoning usually follows the consumption of meat, fish or milk—especially meat.

It was formerly thought that food poisoning was caused by the presence in food of poisonous alkaloidal substances called ptomaines, produced by putrefactive changes. Neurine and mydaine are examples of such. It is now known that ptomaines are very rarely, if ever, the cause of food

poisoning, but that the usual cause is bacterial contamination of food. It is possible that in the consumption of food highly advanced in putrefaction, such as high game, ptomaines may play a part in the causation of toxic symptoms, but cases of this kind are uncommon.

Ætiology.—*Predisposing causes.*—Contaminated food has a much more serious effect on persons suffering from pre-existing gastro-intestinal disease. Thus the presence of colitis or enteritis greatly increases the susceptibility of the patient to bacterial food poisoning, and the resulting symptoms are likely to be more severe than in a person previously healthy. Dysentery or post-dysenteric colitis has a like effect. Starvation or malnutrition increases the susceptibility to bacterial food poisoning, and emptiness of the stomach at the time of taking of contaminated food is likely to lead to the earlier onset and greater severity of the symptoms produced. The above considerations help to explain the remarkable fact that sometimes when several persons partake of the same unwholesome food some may suffer from serious symptoms of food poisoning, while others may only have very slight symptoms, or even be unaffected. Young children are much more susceptible. In hot climates bacterial food contamination is likely to be followed by a very rapid development of bacterial poisons. Dust, flies, dirt and insanitary conditions generally are likely to favour the contamination of food with the bacteria of food poisoning. Careful storage of food in proper safes, where it can be kept cool and free from contamination, is most important.

Meat poisoning may be due to contamination of the flesh during the cutting-up process by the butcher, or the meat may be contaminated either in the process of cooking or afterwards, owing to lack of care in storage.

Sausages.—Many epidemics of poisoning have occurred from infected sausages. This can be readily understood, since the process of mincing, which the meat undergoes, renders it liable to contamination. Moreover, in sausages it is easy for unwholesome meat to be used, with little possibility of detection. The fact that sausages are made with raw or only partly cooked meat, and that they are frequently eaten merely smoked, with little or no cooking, still further adds to the risk. One special organism, the *Bacillus botulinus*, has frequently been found associated with sausage-poisoning.

Tinned meat.—This has been frequently the cause of food poisoning. The meat may be contaminated by poisonous bacteria before tinning, and though the process of canning, by the heat applied, may kill the microbes, yet the toxins may not be destroyed, and these will give rise to symptoms of poisoning when the food is eaten. During the war tinned meat was consumed in enormous quantities by our troops. Very few cases of food poisoning from tinned meats were recorded, and in those cases where investigations were made the cause of the poisoning was traced to infection of the food after the tins had been opened.

Fish.—Numerous epidemics of food poisoning have been due to eating fish. Those have been due to the contamination of the fish with bacteria of the type already described, and the resulting symptoms have been similar in character. Cooking the fish—boiling or frying—may not entirely destroy the toxins present.

Shellfish.—These are frequently grown in waters contaminated by sewage, and microbes of disease get ready access to them. Mussels, oysters, lobsters, crabs, etc., have frequently caused severe attacks of food poisoning, and

commonly the shellfish appeared perfectly fresh, with no objectionable taste or smell.

Tinned fish.—This, like tinned meat, may give rise to poisoning from the contamination of the food by bacteria before canning. It is important to remember that tinned fish, even if wholesome at the time the tins are opened, is very liable to bacterial contamination. It should never be kept, but should be eaten on the day of opening.

Vegetables and fruit.—These may, if contaminated by bacteria of the type described, give rise to the disease. Since, however, the bacteria find vegetables an unsuitable medium for growth, outbreaks of food poisoning from vegetables are uncommon.

Milk.—Milk has on several occasions been the cause of outbreaks of food poisoning, and the organisms above quoted have been found present in the affected milk. If milk is infected with the microbes, all that is necessary is a suitable temperature for their growth, and it speedily becomes a dangerous article of food. It is readily understood, therefore, that these cases are of much commoner occurrence in the warm weather of summer.

W. H. WILLCOX.

BACTERIOLOGY.—Hitherto the term food poisoning has been limited to a clinical entity, characterised by an epidemic outbreak of acute gastro-enteritis among a group of individuals who have partaken of some common article of food. The bacteriological details have been subsequently worked out in the laboratory.

With the increase of routine bacteriological examinations of the intestinal contents in cases of chronic illness or recurrent gastro-intestinal disturbances, coupled with the enormously increased exactitude made possible by the introduction by Browning of enrichment methods, it is becoming increasingly apparent that a large number of infections exist which can only be generically described under the term Chronic Food Poisoning. This latter class of case is quite distinct from that described as acute epidemic food poisoning, and formerly described as ptomaine poisoning, under the mistaken idea that the symptoms were due to an alkaloidal-like group of substances produced in food commencing to putrefy by bacteriological action, which substances were not destroyed by heat.

It has long been recognised, however, that acute epidemic food poisoning is caused by bacterial contamination of imperfectly cooked food, and that the consequent infection in the human consumer has a definite incubation period, though such period may vary in length according to the concentration of bacterial poisons present in the contaminated food. There is considerable evidence, moreover, that the special bacilli concerned in acute food poisoning epidemics, are bacilli that tend to inhabit or infect the intestines of animals whose flesh is used for human consumption.

Both forms of food poisoning are caused by infections with one or other members of a large group of bacilli that have the common characteristic of not being capable of fermenting lactose, in which respect the group is allied to the bacilli of typhoid fever and the dysenteries. This group of bacilli has had various names suggested; for instance, Durham proposed the term "intermediate group," Trautman, "paratyphoid group," while Lignières

suggested the "Salmonella group," after Salmon who discovered the bacillus of hog cholera, restricting the term, however, to that group of bacilli which has the cultural and morphological attributes of the bacillus of hog cholera. It will be seen that the terms paratyphoid and Salmonella have meanings which are hardly comprehensive enough, and the term "intermediate group" does not seem to have any advantage over the term "bacilli of the food poisoning group."

ACUTE EPIDEMIC FOOD POISONING.—Till recently, it was held that this disease was caused by food infected with *B. paratyphosus* B, or *B. enteritidis* *gaertner*. The question was, however, settled by Bainbridge, who published his results in the Milroy Lectures of the Royal College of Physicians in 1912. He differentiated the *B. enteritidis aerrycke* from paratyphoid B, and showed conclusively that as a cause of epidemic food poisoning paratyphoid B was not to be considered. On the continent of Europe this differentiation has not been recognised, the terms paratyphoid B and *B. aerrycke* being merely used as labels to indicate the source of two strains of the same species. Yet Bainbridge finds that all bacilli causing outbreaks of food poisoning in Germany that had come under observation by him are strains of *B. aerrycke*. The result of Bainbridge's work was to establish the fact that, with very few exceptions indeed, epidemic food poisoning is caused by *B. aerrycke* or *B. gaertner*.

Chronic food poisoning differs from the epidemic type in that it is met with in individuals with no relationship, or no recent relationship, to epidemics of food poisoning. It is usually diagnosed in the laboratory, though a history of recurrent attacks of gastro-enteritis lasting perhaps over a number of years, and possibly dating from a typhoid-like illness, may suggest the presence of a member of the food poisoning group of bacilli. Such infections are not infrequently met with in cases of colitis, or "intestinal toxæmia," and again may be disclosed when intestinal examinations with reference to a possible overgrowth of streptococci, in connection with rheumatoid conditions, are being made. These infections do not throw any light, perhaps, on the rheumatic state, but not infrequently account for associated conditions.

The varieties of bacilli involved in chronic food poisoning are possibly numerous, but reference can only be made to some seven or eight which have been to some extent worked out.

The main characteristics of the better known members of the food poisoning group will be considered under their individual names, while their sugar reactions will be tabulated in an abridged and comparative form subsequently.

***B. paratyphosus* A.**—This bacillus has never been identified with an epidemic of food poisoning, but being a member of the paratyphoid group, it has close relationship with the food poisoning group generally. Originally described by Schottmüller, it is only found in England in individuals returned from India and the East. In India, however, it is so common that it has been stated that paratyphoid fever connotes an infection with this bacillus. Morphologically, it resembles typhoid bacilli more than the other members of the group, and though it has the same sugar reactions, it forms less gas, in glucose, mannite and dulcitol, than they do. It is definitely differentiated from the other members of the group, however, by specific serum reactions.

***B. paratyphosus* B.**—Also first isolated by Schottmüller. It is in England the common cause of paratyphoid fever, and formerly it was thought to be

a common cause of epidemic food poisoning. Bainbridge, however, by means of absorption tests showed that it was a distinct organism from *B. enteritidis aertrycke*, with which, owing to identical agglutination reactions, it had been hitherto confounded. This differentiation was confirmed by Dean by means of complement deviation tests. Bainbridge further identified the bacillus with infections clinically resembling mild typhoid fever, while in only one case did he, in association with Dudfield, find paratyphoid B causing an outbreak of acute gastro-enteritis. The bacillus morphologically resembles the coliform group of bacilli rather than typhoid.

B. enteritidis aertrycke.—This bacillus takes its name from the village of Aertrycke in Belgium, where De Nobele isolated it from cases of an epidemic of food poisoning. It was, as pointed out above, regarded as paratyphoid B till differentiated therefrom by Bainbridge, and is still so regarded on the Continent, whence arise the German statements that paratyphoid B is concerned in epidemic food poisoning. The bacillus is identical with the bacillus of hog cholera, *B. suispestifer* and *B. cholerae suis*. It is said to be a normal inhabitant of the intestine of swine on the Continent. This fact may account for the observation that epidemics of food poisoning on the Continent are more frequently associated with the consumption of imperfectly cooked pork than with other flesh foods. The bacillus resembles paratyphoid B in all respects, with the exception of the absorption and complement fixation reactions.

Since *B. aertrycke* was recognised as a distinct variety many epidemics have been traced to it, and different strains of the organism have been recognised. Thus the Newport strain, recovered by Schutze in 1915 and the Mutton strain isolated at Newcastle by Hutchens are well known. A severe epidemic of food poisoning occurred in a depot in France in April 1918, and was carefully investigated by Marrian Perry and Tidy. The outbreak was shown to be due to the Newport strain of Aertrycke, and the conclusion arrived at was that it was caused by bacterial contamination of food by a "chronic carrier," and subsequent cases were caused by contact with "acute carriers."

It is probable that nearly all recorded epidemics of food poisoning said to be due to paratyphoid B were in reality due to *B. aertrycke*.

B. enteritidis gaertner.—Isolated by Gaertner at Frankenhausen in 1888 from the spleen of a patient who died as a result of partaking of a meal in which the bacillus was found.

Morphologically and culturally it resembles paratyphoid B and *B. aertrycke*, but is sharply differentiated therefrom by specific agglutination tests. It seems to be a less common cause of epidemics of food poisoning than *B. aertrycke*, but such epidemics have been recorded by van Ermengem at Moorsele, Brussels and Gand, and by McWeeney at Limerick. Bainbridge mentions eleven epidemics. It has been identified with epizootic disease in rats and rabbits by various observers.

B. typhi murium, Danysz's virus, and the bacillus of psittacosis, have now been identified with the paratyphoid B, *B. aertrycke* and *B. gaertner* group, or *Salmonella* group.

B. asiaticus (Castellani).—This bacillus was found but rarely prior to the war except in cases who had resided in India. Indeed, prior to that date the writer had only observed it once apart from residents in India and the

East, the case being that of a man who had apparently had an attack of food poisoning acquired from oysters eaten in Havana, and was at the date in question the subject of recurrent attacks of gastro-enteritis. During and since the war, however, *B. asiaticus* has become increasingly frequent in patients who have not left England, but who may have had more or less direct contact with soldiers from the East. The first such case the writer saw was that of a woman whose husband was invalided with "dysentery" from Gallipoli. In the writer's experience it is at this date decidedly more frequently met with than paratyphosus B.

The bacillus of epidemic jaundice.—This is a common organism, infections with which are, as a rule, much less severe than are those of the paratyphoid group, though a case of septicæmia has been observed in a colleague of the writer's, who had an illness at first suggesting enteric. On the other hand, the organism may swarm in the intestine of an individual who shows no symptoms of food poisoning. In one case observed by the writer it was found in not far from pure condition in the stool of an individual who had recently had a surfeit of Strasbourg pie, but exhibited no intestinal symptoms. A companion *pâté* was found to be heavily infected with the same bacillus.

It is possible that the difference in virulence just alluded to may mean that more than one variety of bacillus gives the sugar reactions characteristic of the bacillus of epidemic jaundice. Douglas has, in fact, shown that there are differences in agglutinating power. On the other hand, it may be that a bacillus which gives one individual a septicæmia is only able to effect a lodgment in another individual, without producing any immediate obvious symptoms of infection.

B. dysenteriae morgan.—This bacillus has cultural affinities to the food-poisoning group. It was found by Morgan in 63 per cent. of a series of cases of summer diarrhœa investigated by him. It occurs in a small proportion of cases of chronic food poisoning, and there is some evidence to suggest that a certain proportion of intractable skin affections are associated with the presence of this bacillus in the intestine.

B. fecalis alkaligenes.—This bacillus resembles in several respects the typhoid bacillus, but can be differentiated therefrom by the sugar reactions and by agglutination. Its presence in the intestine is associated with much fœtor. It is sometimes, at least, pathogenic in that it may be the cause of ulceration of the intestine, and stricture following cicatrization of such ulcers has been noted.

B. pyocyaneus, the organism associated with blue pus, must be mentioned, though there is perhaps little evidence to connect it with food poisoning. It may be the cause of acute ulcerative colitis, but usually its presence is associated with intestinal toxæmia without acute symptoms. In culture, its property of forming the characteristic green, blue or even black pigment, suffices to differentiate it, while its sugar reactions separate it from the rest of the group, with the exception of *B. alkaligenes*. It, however, grows with much more luxuriance on ordinary medium than does this latter bacillus.

As has been indicated above, the ultimate classification of any member of this group must rest upon specific serum agglutinations, and in the case of *B. paratyphosus* B and *B. aertrycke*, absorption tests are necessary. But a provisional and useful classification is possible by means of sugar reactions.

392 DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

Monosaccharides, disaccharides and polysaccharides, and some of the allied alcohols have been used. Whatever the substance employed it must be pure, and the basis of the medium containing it must be glucose-free. The list of such substances available is a long one, but for practical purposes may be usefully abridged to five, namely, lactose, glucose, mannite, dulcite and saccharose. This group of five sugars was chosen for routine work by Cap-

	Lactose.	Glucose.	Mannite.	Dulcite.	Saccharose.	Indole.	Motility.	
<i>B. paratyphosus A</i> . . .	-	+	+	+	-	-	-	Definitely classified by agglutination.
<i>B. paratyphosus B</i> . . .	-	+	+	+	-	-	-	Can only be differentiated one from the other by absorption or complement deviation tests. The common agglutination reaction differentiates them from the other members of the group.
<i>B. acertrycke</i> . . .	-	+	+	+	-	-	-	
<i>B. guertner</i> . . .	-	+	+	+	-	-	+	Definitely classified by agglutination.
<i>B. asiaticus</i> . . .	-	+	+	-	+	+	-	The only non-motile member of the group.
<i>B. of epidemic jaundice</i>	-	+	+	-	-	+	+

(+) indicates formation of acid and gas in sugar tubes, or formation of indole, or active motility, respectively.
 (-) indicates the converse, respectively.

tain S. R. Douglas, and the experience of over 10 years confirms the wisdom of his choice.

The specimens to be examined should invariably be passed through dilutions of brilliant green in peptone water. The writer uses two strengths of this stain of about 1 in 300,000 and 1 in 1,000,000 respectively. The investigation becomes infinitely more delicate in consequence, and constant object lessons occur of the extreme value of the method introduced by Browning.

The foregoing bacilli are the common abnormal bacilli found in acute and chronic food poisoning. The list is not to be taken as in any way exhaustive. There are, for instance, bacilli giving the sugar reactions of the paratyphoids,

which do not agglutinate with the specific sera of the members noted above. The term paratyphoid C has been used to denote some at least of these atypical strains.

There is more than one variety of Morgan's bacillus, and Castellani has described a *B. pseudo-asiaticus* which ferments dulcete, specimens of which are occasionally found in the human stool in this country.

Again there appears to be an indefinite group of bacilli which have been termed the late lactose fermenters. These tend to show the sugar reactions of the paratyphoid group for 48 hours, and then lactose tends to become fermented. This group appears to be abnormal as an inhabitant of the human intestine, but the pathogenicity thereof has not been worked out.

Finally, there is a group of bacilli which give the paratyphoid sugar reactions as far as acidification of the medium is concerned, but no gas formation occurs. This group, apparently abnormal to the human intestine, has not been classified.

JOHN MATTHEWS.

Pathology.—The *post-mortem signs* are those of an acute gastro-enteritis, with evidence of a general bacterial infection or toxæmia. When diarrhœa has been very severe, the tissues of the body may be shrunk from drainage of fluid. Rigor mortis sets in early. The stomach may show some redness from congestion, and, especially where vomiting has been severe, there may be small submucous hæmorrhages. Much mucus is generally present, but the stomach contents are free from blood. The inflammatory signs in the small intestines are usually more marked than in the stomach, which is an important distinction from chemical irritant poisoning, such as that caused by arsenic. The mucous membrane is swollen and congested, and the lymphoid follicles and Peyer's patches often show marked swelling and congestion. The signs are often more marked in the ileum than in the upper part of the small intestine. The mucous membrane of the large intestine may be swollen and congested, and the lymphoid follicles much enlarged. The contents are liquid and may contain much mucus. Small submucous hæmorrhages may occur in any part of the intestinal tract. The spleen is congested and soft, and in cases where infection with living bacteria has occurred, it may be enlarged. The liver and kidneys may show cloudy swelling or fatty degenerative changes. It is important to remember that in fatal cases of food poisoning the macroscopic morbid changes found post-mortem may be very slight.

Symptoms.—*Latent period.*—The period which elapses between partaking of the contaminated food and the onset of symptoms may vary from a few hours to 3 or 4 days. Usually, however, the latent period is short, from 2 to 6 hours being common. The greater the amount of preformed bacterial toxins in the food, the earlier will be the appearance of symptoms. The latent period is influenced by other conditions. Thus, if the poisonous food is taken on an empty stomach, the symptoms will come earlier. Again, if the infected food is taken alone, the symptoms will occur earlier than if it is taken with a considerable amount of other wholesome food. In the Welbeck epidemic, investigated by Dr. Ballard, the latent period was accurately determined in 51 cases. In 5 it was 12 hours or less; in 34 it was 12 to 36 hours; in 8 cases it was 36 to 48 hours.

The symptoms are of sudden onset, and in some cases a rigor may usher in the attack. The symptoms are usually those of gastro-enteritis, namely, furred tongue, severe abdominal pain and a rise of temperature, and often vomiting and purging. The stools are liquid and very offensive, and sometimes contain mucus and blood. In severe cases there may be cramps in the calves of the legs, and collapse with heart weakness, and the patient may become cold and blue owing to the feeble circulation consequent on a state of extreme collapse. In some cases rashes appear of the type of "erythema," or "urticaria," and in severe cases "purpura." Often the severe cases present the symptoms of bacterial infection of the blood (septicæmia) and such complications as pneumonia are then likely to occur. In some attacks of food-poisoning, especially those due to contaminated fish, the toxins appear to act especially on the blood vessels, producing rashes with considerable swelling of the skin (erythema and urticaria), which are associated with fever and a furred tongue, though there may be but little or no diarrhœa and vomiting.

Diagnosis.—The diagnosis is usually clear, from the sudden onset of typical symptoms a short period after taking contaminated food. It cannot be too strongly emphasised that the symptoms of bacterial food poisoning are almost identical with those of poisoning by arsenic or antimony or other chemical irritant poison. An analysis of the vomit, fæces and urine for arsenic and irritant chemical poisons at once renders the diagnosis clear.

Course and Prognosis.—In mild cases, the symptoms clear up in a few days and the patient is completely restored to health. Where there is an actual infection with living pathogenic organisms the illness may run a course similar to that of typhoid fever. Severe cases may present symptoms so acute as to resemble true cholera, and in these the prognosis is grave.

Complications and Sequelæ.—An attack of bacterial food poisoning may be complicated by the development of a specific disease, such as enteric or paratyphoid fever, owing to the living organisms of this disease being also present in the contaminated food. After an attack of bacterial food poisoning there is sometimes left a latent bacterial intestinal infection so that the patient, in addition to being a "carrier" of disease, is liable to recurring attacks of enteritis from slight causes.

Treatment.—*Prophylaxis.*—The importance of this has been already indicated above. The greatest care should be taken in the avoidance of articles of food likely to be contaminated, and the efficient cooking of food whereby any living bacteria present are destroyed is a great safeguard. After cooking, rigid care should be taken in the storage of food to prevent contamination.

General treatment.—Rest in bed is essential. The diet should consist of liquids, such as water, albumin water, chicken broth or whey. Milk is often best avoided; peptonised milk or citrated milk (2 grains of citrate of soda to the ounce of milk) diluted with an equal quantity of water may be given. The feeds should consist of 3 or 4 ounces of liquid every 2 hours, and to these 1 or 2 teaspoonfuls of brandy may be added with advantage. As the symptoms improve, the dietary is gradually increased. Hot applications to the abdomen are advisable. Where there is much pain and diarrhœa without collapse, the hypodermic injection of morphine is advisable. Colon irrigations with 2 pints of normal saline are of value in cases with diarrhœa and slight collapse. In cases with choleraic symptoms and marked collapse, sub-

cutaneous or intravenous injection of normal or hypertonic saline should be given. A mixture of bismuth and soda with hydrocyanic acid is of value in relieving the gastric irritation, and to control the diarrhoea bismuth salicylate in 10 or 15 grain doses is useful.

The treatment of a case of food poisoning should be accompanied by periodical bacteriological investigations of the stools, and a case cannot be regarded as cured until three successive bacteriological examinations made at intervals of 2 or 3 days have shown freedom from infection with the pathogenic organisms of the disease.

W. H. WILLCOX.

BOTULISM

Synonyms.—Sausage poisoning, Allantiasis.

Definition.—A rare, but very fatal form of poisoning due to the effect on the nervous system of the toxins of the *Bacillus botulinus*. Botulism belongs to the food-poisoning class of disease, but differs from the old conception of ptomaine poisoning, in which the actual poison was supposed to be altered food product, on the one hand, and from the bacterial food poisonings, in which an actual infection is transmitted, on the other hand. Ptomaine poisoning has now only historic interest, and the bacterial food poisonings fall into the group of infections known as enterica, in which a period of incubation is involved, and more or less symptoms of gastro-enteritis occur. Botulism depends upon the ingestion of a certain minute quantity of preformed toxin, and in no way upon the introduction of the bacillus or spores thereof.

Ætiology.—Sausage poisoning was known in Wurtemberg as long ago as 1820, and it gradually came to be associated with the eating of smoked sausages that were not consumed in the fresh condition. In 1895 an outbreak occurred in Elezelles, a village in Belgium, which was very thoroughly investigated by Van Ermengem. He recovered a bacillus, to which he gave the name *B. botulinus*, from the ham partaken of by all the patients, and from the spleen of one of the fatalities. The ham itself, which was in no wise decomposed, caused typical symptoms of the disease, when inoculated into animals, as did also the recovered bacillus. Other outbreaks occurred in Europe, mostly associated with the eating of partially cooked flesh, in which storing constituted a definite part of the ripening process, no cooking being employed at the period of consumption. During the last fifteen years botulism has excited considerable anxiety in America, chiefly in California, and is there associated with the eating of home-canned vegetables. Contrary to the generally accepted views, it was found by Meyer that the bacillus was a natural inhabitant of soil, in its virgin state. It was found more abundantly in soil from high mountains and virgin forests than in soil from crowded stock-yards and highly cultivated gardens.

Bacteriology.—*B. botulinus* is a large gram-positive bacillus, 4–9 μ long by 0.9–1.2 μ broad. It stains well with ordinary dyes, but tends to lose Gram's stain if care be not taken. It possesses flagella, and is slightly motile. It forms terminal or sub-terminal spores, especially, in the case of most strains, at a temperature between 20° and 25° C. Likewise the optimum temperature of growth for most strains is between 20° and 30°. The bacillus is a strict anaerobe, and will only grow in slightly alkaline or neutral media,

though in this connection may be mentioned an outbreak that followed the eating of some tomato-onion-chilli sauce found to be heavily infected, and of an acid reaction. In deep stab, culture growth occurs as a thin whitish streak, not reaching to the surface; later the medium is cracked by the abundant formation of gas. With strict anaerobiosis the organism grows well on the ordinary media. Gelatine is liquefied. There are two types, A and B. They are readily separated by the fact that chickens are susceptible to type A only. Three different strains are named. They are the Boise (type A), the Nevin (type B), and the Memphis (Type A). Type A is more common on the Pacific Coast of America, while type B is more common in the Eastern States, and in Europe. The strains differ in their behaviour to heat. Most strains are killed by boiling, but the Boise strain can survive boiling for an hour, and consequently steam pressures are necessary to sterilise adequately food products contaminated therewith. Dr. Meyer mentions that of 17 strains isolated from different food products the spores varied in their resistance to a temperature of 100° C. from 10 to 230 minutes. The toxins of the various strains all seem to be destroyed by temperatures slightly less than 80° C., the Boise strain toxin being destroyed by 10 minutes at 73° C. The toxicity of the toxin can be so high that 0.0001 c.c. of the filtrate of a culture grown at 35° C. proved lethal to a guinea-pig of 350 grammes. The Boise strain also differs from the others in that it grows best at or about body temperature, and has a characteristic odour.

Symptoms.—There being no incubation period, there are no symptoms prior to the onset of the dizziness and diplopia that constitute the first signs of the involvement of the cranial nerves. Occasionally there are some abdominal pains, accompanied by vomiting, and there is some weight in the suggestion that the vomiting denotes an unusually heavy dose of toxin, for vomiting usually presages a fatal termination. Other cranial nerves are gradually affected, the larynx becomes involved and speech may be lost, and later respiration and the heart's action become affected, by reason of the involvement of the spinal accessory and vagus. Consciousness is not lost. Obstinate constipation is the rule, in sharp contrast to the diarrhoea usually associated with enterica. Botulism differs from encephalitis lethargica in that there is an entire absence of the somnolent state characteristic of the latter condition, while the absence of fever differentiates it from anterior poliomyelitis.

Prognosis.—This is very grave, the mortality being more than 50 per cent. In some outbreaks, for instance that of Loch Maree, every case proved fatal. Death may take place in 36 hours, or may be delayed for a week.

Treatment.—Antitoxin given experimentally with toxin prevents the fatal issue of the latter. In practice antitoxin treatment will only be available for use in the later or less severe cases of an outbreak. Measures to promote elimination of toxin are called for, but are handicapped by the obstinate constipation. Alcohol appears to have a distinct effect in "denaturing" the toxin, and may, therefore, be given freely, partly for this effect and partly for stimulation. Strychnine should also be given. Ether anaesthesia is said to delay fixation of toxin by the tissues, and if so it might be usefully employed while antitoxin was being procured. Some relief from the mental distress due to the absence of unconsciousness would also accrue.

It is to be noted that the Loch Maree attack of botulism, the first recorded in Great Britain, occurred after the first edition of this book was written. In

consequence of this outbreak a very elaborate investigation was initiated, in the course of which much new light on botulism emerged. This was detailed in a book published by Dr. Gerald L. Leighton, together with a mass of entirely new work recorded in America, chiefly by Professors Meyer and Dickson.

JOHN MATTHEWS.

SECTION VI

DISEASES OF METABOLISM

BASAL METABOLISM

By basal metabolism is meant the metabolism of an individual when he is lying down in as complete a condition of rest as possible, and has taken no food for 14 hours—the post-absorptive state.

Basal metabolism is increased by the intake of food, and the amount and nature of the food determines the amount of its increase. Exercise also increases metabolism, and considerably so. In order to obtain an accurate estimate, certain precautions are therefore necessary. It is customary to prescribe a light evening meal some 14 hours before the test, and to make the subject lie down, with the muscles in complete relaxation, for half an hour. The actual estimation may be performed in two ways, namely, by the direct method and by the indirect method, the latter being easier but not so accurate. In the direct method, the air which is breathed out under the standard conditions is collected for 10 minutes and the total volume measured. The amounts of carbon dioxide and oxygen present are estimated by means of a Haldane gas analysis apparatus. By this means the Respiratory Quotient (R.Q.), i.e. the ratio of the volume of carbon dioxide given out to the volume of oxygen taken in, and the amount of oxygen used may be determined with great accuracy. In the indirect method, the subject breathes oxygen which is in a closed system for 10 minutes. The carbon dioxide formed is absorbed with soda lime, and the oxygen which has been used is calculated from the amount of gas which has disappeared from the system. The surface area of the body in square metres is then estimated from the weight and height of the patient by means of the nomograph (Fig. 7). The amount of oxygen which has been used by the patient is then expressed in terms of one square metre of body surface per minute. The next step may be done in one of two ways. (1) The amount of oxygen per square metre of body surface is compared with the amount of oxygen which an average subject of the same age and sex consumes (see Table I.). (2) The number of heat calories which the oxygen would give when burnt under standard conditions is ascertained from the tables of oxygen values, and this result is compared with the calories per square metre of body surface which an average subject of the same age and sex would consume (see Table II.). The final result in either method is expressed as plus or minus x per cent. as compared with the average values in the case of normal people.

It is accepted that the subject is normal if the figure lies within the limits of plus or minus 10 per cent. Important variations occur when the thyroid is affected. If the gland is atrophied or absent (myxoedema), the basal rate may be as low as minus 40 per cent.; while if it is overactive

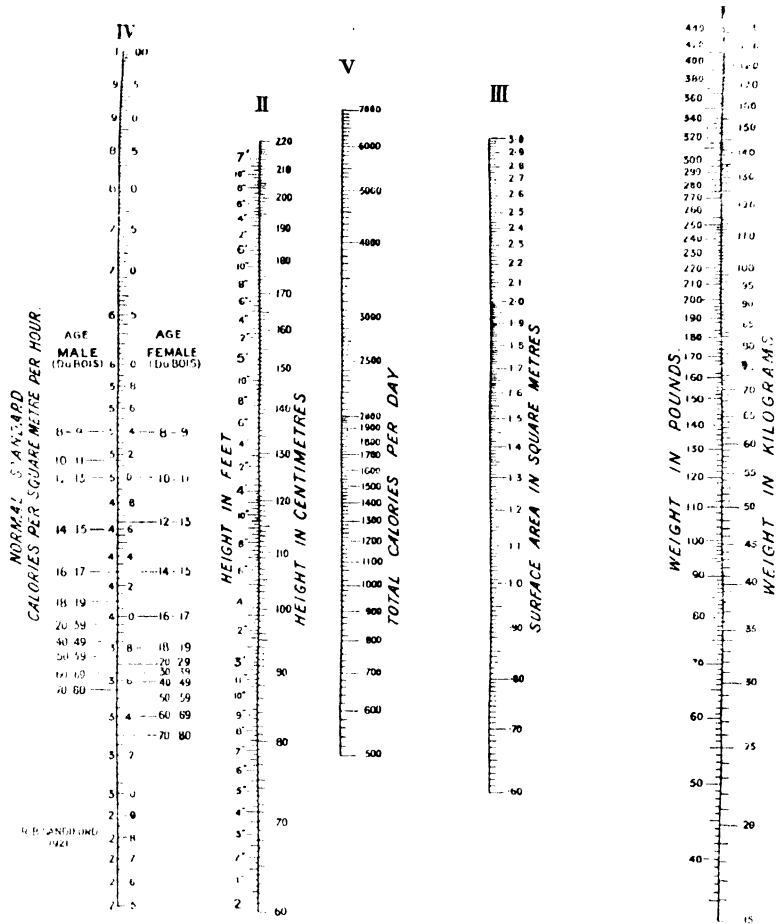

FIG. 7. — BOOTHBY AND SANDIFORD'S NOMOGRAPH.

The weight in pounds or kilogrammes is shown on Scale I. The height in inches and centimetres is shown on Scale II. The surface area in square metres is shown on Scale III. The normal standard calories per square metre of body surface per hour is shown on Scale IV. The total calories per diem is shown on Scale V.

Directions.—Keep the chart flat. Use a flexible ruler with a straight edge, or a strip of stiff paper, such as a postcard. (A) Locate the position of the weight and height on Scales I. and II. respectively. Apply the straight edge of the ruler, and note where it cuts Scale III. Read the figure on Scale III., which will give the surface area of the body in square metres. (B) Locate the surface area on Scale III., and the normal standard calories per square metre per hour for the age and sex of the subject on Scale IV. Apply the straight edge of the ruler, and see where it cuts Scale V. Read this figure, which gives the total basal calories per 24 hours.

Large scale nomographs may be obtained from W. B. Saunders Co., West Washington Square, Philadelphia, U.S.A., or from H. N. Elmer, 1641 Monadnock Buildings, Chicago, U.S.A.

(exophthalmic goitre), the basal rate may be very high, varying from plus 15 to 20 per cent. to 100 per cent. or even more. In starvation and severe undernutrition, the basal rate may be below minus 10 per cent.

ACIDÆMIA, ALKALÆMIA, AND ALLIED CONDITIONS

Definitions.—*Acidæmia* signifies that there is an increase in the H ion concentration of the blood. This may be due to an increase in the amount of CO₂ in the blood, or to an increase in the fixed acids of the blood. In the latter case, the acid unites with the bases and lowers the amount of CO₂ which can be carried in the blood. The name *acidosis* has been applied to this latter condition, but it has given rise to so much confusion that it is better to abandon the name altogether, and to speak of a decrease in the alkali reserve of the blood. *Alkalæmia* signifies that there is a decrease in the H ion concentration of the blood. The name *alkalosis* has been used to describe the conditions in which there is an increase in the alkali reserve of the blood, but, for the same reason as for acidosis, it would be better to drop the name altogether, and to speak of an increase in the alkali reserve.

Physiology.—The reaction of a fluid is best expressed in terms of the concentration of the H ions. It is known that the H and OH ions react in accordance with the equation $(H) \times (OH) = (H_2O)$, and that the equilibrium reached obeys the law of mass action. This is expressed as follows: $(H) \times (OH) = K$. The brackets signify concentrations and K is a constant, (H_2O)

which is dependent on the temperature. Since the mass of the water is enormously greater than the mass of (H) and (OH) ions, (H₂O) may be regarded as a constant, and the equation may be written in a simpler form $(H) \times (OH) = K$. The constant K is called the dissociation constant of water, and at 15° C. has the value of 10^{-14} . If a solution is neutral, the concentration of H and OH ions will be equal, i.e. $(H) = (OH) = 10^{-7.07}$, since $(H) \times (OH) = 10^{-14}$. An acid solution has a greater concentration of H ions than OH ions, and it follows from the equation that an increase in the concentration of the H ions results in a decrease in OH ions, since K is a constant.

It is inconvenient to express (H) as a negative and fractional power of 10, and Sørensen has introduced a notation which avoids this difficulty. Since $(H)=10^{-7.07}$, -7.07 is, by the definition of the term logarithm, the log. of the H ion concentration of water. Sørensen disregarded the negative sign and called the numeral 7.07 the PH value of water. It follows from this that as the PH value of a fluid increases, the H ion concentration and, therefore, the acidity diminishes, because a large negative number is actually smaller than a small negative number. If a fluid has PH=7.07 it is neutral, like water; if it has PH=1 it has the acidity of decinormal hydrochloric acid; while if PH=13.2 it has the alkalinity of decinormal caustic soda. Normal blood has a PH which is slightly alkaline, and lies between 7.30 and 7.50.

It is very easy to change the reaction of a fluid like water, which only contains H and OH ions. Blood, however, is a very complex fluid, since it contains salts of weak acids, such as the acid and alkaline phosphates, and sodium bicarbonate, which, together with the hæmoglobin and proteins, act as "buffers" and prevent the reaction of the blood being easily changed. Further, other regulating mechanisms are at work, since urea can be split up into carbon dioxide and ammonia; the former can be excreted by the lungs, while the latter can be used to neutralise an acid. The kidney can excrete acid or alkaline salts which may be in excess, and thus help to keep the reaction of the blood constant. Much attention has been paid to the regulation of the blood by means of the sodium bicarbonate and carbon dioxide. In this process, the respiratory centre plays a very important rôle, since, if it is damaged in disease or by drugs, such as morphine, the regulating mechanism is upset. The H ion concentration of a fluid which contains only weak acids and their salts has been shown to be equal to $\frac{(H_2CO_3)}{(NaHCO_3)} \times K$, where

K is a constant, and the brackets signify concentrations. The significance of this equation is more easily appreciated if it is written as follows:

$K = (H) \times \frac{(NaHCO_3)}{(H_2CO_3)}$. If there is an increase in the H ions of the blood,

there must be a decrease in the size of the fraction $\frac{(NaHCO_3)}{(H_2CO_3)}$, since the value

of K does not alter. This can be done in two ways, either by decreasing the amount of $NaHCO_3$ or by increasing the amount of H_2CO_3 . If, on the other hand, the H ion concentration is decreased, K can be kept constant, by increasing the amount of $NaHCO_3$ or by decreasing the amount of H_2CO_3 . The amount of $NaHCO_3$ which is carried in the blood is termed the alkali reserve of the blood (van Slyke). It is calculated as the amount of CO_2 which can be taken up by blood at a pressure of 40 mm. of CO_2 . The figure for normal blood lies between 40 and 55 vols. per 100 vols. of blood, while the figure for plasma is 53-58 vols. per 100 vols. of blood. The changes in the alkali reserve can be estimated directly by van Slyke's method. The estimation of the amount of CO_2 in the alveolar air is of assistance in this connection, since in health the CO_2 is present at the same tension in the blood and alveolar air. When the alkali reserve is reduced, there will also be a decrease in the percentage amount of CO_2 in the alveolar air, which may keep the fraction $\frac{(NaHCO_3)}{(H_2CO_3)}$ constant, and thus prevent any change

in the PH. This will necessitate an increase in the volume of the respiration, since the same amount of CO_2 will be excreted under similar conditions of exercise and food. The increased depth of respiration is seen in the "air hunger" of diabetic coma.

~~A simple example of the change in the alkali reserve is seen when a meal is eaten (Dodds).~~ The excretion of hydrochloric acid into the stomach is followed by an increase in the percentage amount of CO_2 in the alveolar air. After a length of time which varies with the individual but is usually about one hour, the percentage amount of CO_2 decreases and falls below the original value. It returns to the original value in about 2 hours. If no food be eaten there is no change in the alveolar CO_2 .

A diminution in the alkali reserve also occurs when the acetone bodies aceto-acetic acid and β -oxybutyric acid are present in the blood and urine. This condition is usually termed *ketosis*, on account of the acetone bodies. It is a useful term, since it serves to distinguish the condition from the diminution of the alkali reserve due to other causes. The changes which occur

in ketosis are believed to be due to the enolic group $\begin{array}{c} \text{COH} \\ || \\ \text{CH} \end{array}$ of the aceto-

acetic acid, which stimulates the respiratory centre. In severe cases of diabetes, there is often a great decrease in the alkali reserve and alveolar CO_2 , and there may be an actual increase in the H ion concentration, i.e. an acidæmia. A mild degree of ketosis occurs in absolute starvation, carbohydrate starvation and after vomiting. In children a ketosis occurs much more frequently than in adults. It may be very severe in cyclic vomiting, pernicious vomiting of pregnancy, and after chloroform and ether anaesthesia; but it also occurs to a lesser degree after vomiting due to other causes, and in the course of any infectious disease, and also occasionally after large doses of sodium salicylate. When the ketosis is well marked there is always great hyperpnœa, e.g., the "air hunger" of diabetic coma.

Acidæmia is present in patients who suffer from dyspnœa which is due to emphysema and bronchitis. In this case there is an increase in the amount of CO_2 which is carried in the blood. Acidæmia may be present in severe cases of nephritis, especially when the patient suffers from uræmia. The PH of the blood may be as low as 7.12 in uræmic coma. In these cases there is always a decrease in the alkali reserve, but the CO_2 is not decreased in proportion, so that there is an increase in the H ion concentration. Sometimes the hyperpnœa is almost as well marked as in diabetic coma.

The existence of *alkalæmia* is only a recent discovery. It was thought that the blood of individuals who had recently ascended to high altitudes was acidæmic, but it has recently been shown that the symptoms are really due to an alkalæmia. The urine becomes alkaline, owing to the increased excretion of alkalis. The use of alkalis in large doses in the treatment of gastric ulcer may cause loss of appetite, vomiting; and if the alkali is continued the signs of uræmia may develop. Some of the patients who suffer from dyspnœa, due to cardiac failure, have an alkalæmia. The PH of the blood may be as high as 7.90 or higher. The subject is a difficult one, since some

of the patients with cardiac failure have an acidæmia, or the reaction may lie somewhere between an alkalemia and an acidæmia. These differences may be due to the fact that in many cases of cardiac failure there may be a co-existent renal disease. It has been pointed out that acidæmia occurs in uræmic patients, and, therefore, if the dyspnœa is partly due to the cardiac or pulmonary failure and partly to the renal disease, it will be impossible to foretell whether the blood will be acidæmic or alkalemic.

Diagnosis.—This can only be made with certainty by employing the more accurate methods for determining (1) the H ion concentration of the blood (Hastings and Sendroy), (2) the alkali reserve of the blood (van Slyke), (3) the alveolar CO_2 (Haldane and Priestley, Hasselbach, Fridericia), (4) the reaction of the freshly passed urine, (5) the amount of aceto-acetic acid and ammonia in the urine, and (6) the amount of sodium bicarbonate which is necessary to make the urine alkaline. (In health a dose of 5 grammes is sufficient to make the urine alkaline for a short while.)

Prognosis.—This depends almost entirely on the nature of the disease causing the condition.

Treatment.—This should be directed to removing the cause of the condition. The treatment of the ketosis which occurs in diabetes is described on p. 419. In acidæmia, sodium bicarbonate, Ji (4 g.) 4-hourly, should be given together with dextrose Ji (25 g.) 4-hourly, with an abundance of water. The amount of alkali should be reduced as soon as the hyperpnœa becomes less. Small doses of insulin, 10 to 20 units, may be of assistance. The bowels should be kept well open.

In alkalemia, all alkalis should be stopped and acid sodium phosphate, gr. xxx (2 g.) 4-hourly, should be given, besides sugar and water as in acidæmia. The reaction of the blood should be estimated if possible, and the reaction of each specimen of urine should be tested.

DIABETES MELLITUS

Diabetes mellitus is a disease in which the metabolism of carbohydrates, together with that of proteins and fats, is disturbed. The obvious signs of this are the presence of sugar and acetone bodies in the urine.

Ætiology.—(a) *Predisposing causes.*—Diabetes is more common among Jews than Gentiles, and in Frankfurt 31·5 per cent. of the cases were of Jewish descent. It is also very common in a mild form among the natives of India and Ceylon. Heredity undoubtedly plays some part, as many members of a family may be affected. This can partly be explained as being due to the same excesses of diet, especially when the disease develops late in life. But this cannot explain all the cases, especially those which occur among the younger members of the family. The familial form is sometimes very mild, but may be very severe. Joslin obtained a history of heredity in 13 per cent. of his cases. Cases of diabetes in husband and wife occur occasionally, but this is probably due to similarity of living and not to contagion. The disease is more common among males than females. It is commoner between the ages of 40 and 60; these two decades contained 48 per cent. of Joslin's cases, while only 7 per cent. of the cases occurred between the ages of 20 and 40, and 4 per cent. were under 20.

(b) *Exciting causes.*—The disease is often present among elderly people

who (1) take an excess of carbohydrate foods and sugar, (2) are considerably over weight, (3) have a blood-pressure which is considerably raised, and (4) are subject to great anxieties. But the exciting cause of the acute disease which is seen in young people is quite unknown.

Pathology.—The blood normally contains sugar, and the amount varies in health between 80 and 120 mgm. per cent. The total amount of sugar in the blood of a man weighing 65 kilos, or 10 st. 3 lb., would be 4 to 6 grammes, assuming that the total volume of the blood is $\frac{1}{13}$ th of the body-weight, i.e. 5000 c.c. The percentage amount of sugar in the blood remains fairly constant, so long as no food is eaten. A dose of 100 grammes of dextrose will cause a rise in the blood sugar from 100 to 150 to 180 mgm. per cent. The change may be evident in 10 minutes, and usually reaches its maximum in 30 minutes. The sugar returns to its original level in a variable time—60, 90, 120 minutes, depending on the individual (Fig. 8). Provided that the blood sugar does not exceed 180 to 200 mgm. per cent. no sugar is excreted in the urine; but this again is a variable factor, as some people pass sugar at a considerably lower level than 180 mgm. per cent., whereas others do not although the blood sugar rises to 250 to 270 mgm. per cent. A carbohydrate meal produces a similar effect, but the rise is usually slower and more sustained. Protein does not cause any rise in the blood sugar of healthy people, but it does so in diabetic patients.

Some of the sugar which is eaten is burnt at once as the respiratory quotient approaches 1 after the dose of sugar, but the greater part of it must be stored, either in the liver or muscles. A healthy adult can usually eat 100 to 200 grammes of pure dextrose without causing any glycosuria, but the individual variations are great.

In mild cases of diabetes the blood sugar when fasting may be within normal limits, but a dose of 50 grammes of dextrose will raise the blood sugar from 120 mgm. per cent. to above 200 mgm. per cent. The maximum height may be reached in 1, 2 or 3 hours, and then the blood sugar returns slowly to its original level (Fig. 9). Sugar is excreted in the urine all the time the blood sugar is above the threshold of the kidney for the individual, which may be 180 mgm. or 200 mgm. per cent. In the more severe cases the blood sugar is always above the threshold, and sugar is excreted throughout the day. In these cases there is a decrease in the power of burning sugar, and the respiratory quotient does not approach 1 after a meal, and may be below 0.8. When the carbohydrate metabolism is seriously upset, proteins also cause a rise in the blood sugar, as 58 per cent. of the protein molecule is burnt as sugar. The thirst of which the patient complains is due to the excretion of the sugar, as apparently this cannot be excreted without a good deal of water.

When the sugar cannot be burnt properly, the metabolism of fat is also upset, and the fatty acids, aceto-acetic acid, β -oxybutyric acid, and acetone, are excreted in the urine. These are incomplete products of fat metabolism, and cannot be burnt completely in the absence of a certain amount of sugar metabolism. The amount of acetone excreted in the urine is very small; the aceto-acetic acid forms about 30 per cent. and β -oxybutyric acid 70 per cent. of the total acetone bodies if these are present in large amounts. This condition is now called ketosis, instead of acidosis, as usually there is no change in the H ion concentration of the blood.

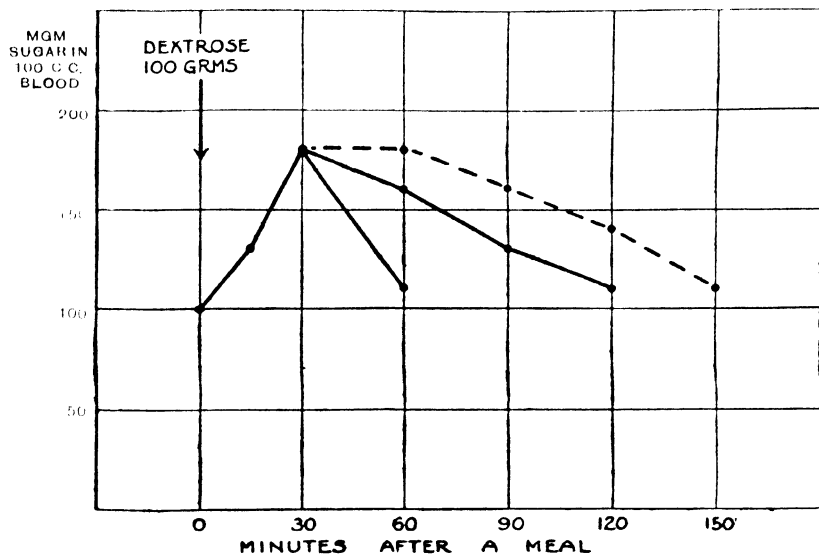

FIG. 8.

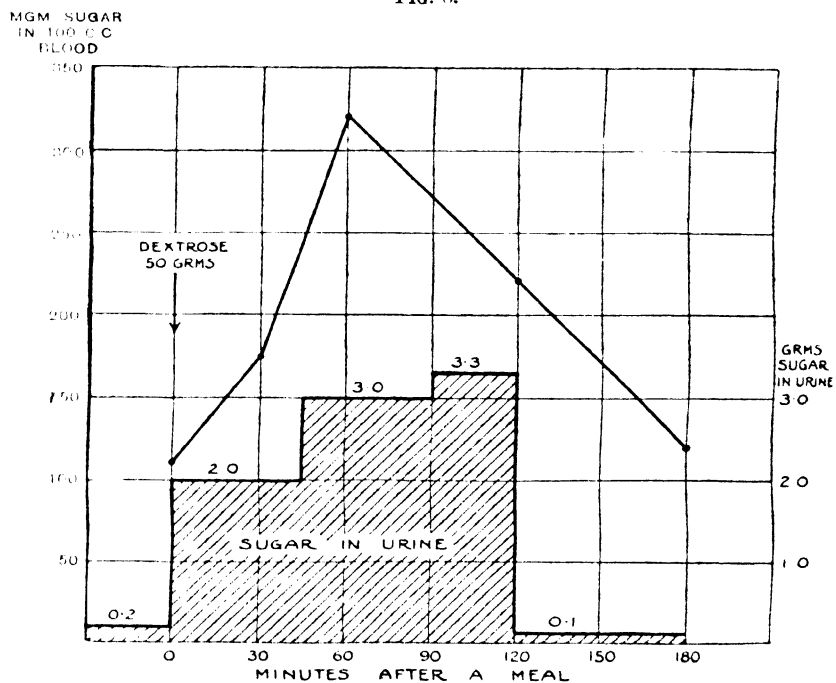

FIG. 9.

The amount of carbon dioxide in the alveolar air is usually over 5 per cent. in healthy persons, but it is reduced when ketosis is present (Beddard, Pembrey & Spriggs, Poulton). It may fall below 3 per cent., but this does not mean that the patient will pass into coma at once, but only that the condition is serious. If it falls below 2 per cent., the patient is usually comatose and is unlikely to recover unless insulin is injected in adequate amounts. The poisonous substance is probably aceto-acetic acid, acting

$$\begin{array}{c} | \\ \text{COH} \\ || \\ \text{CH} \\ | \end{array}$$

not as an acid, but through the enolic group \parallel . This acts on the

respiratory centre (Hurtley and Trevan). The alkali reserve of the blood is much reduced in severe cases and may fall from the normal 44 to 60 vols. per cent. to below 20 vols. per cent.

The sugar metabolism is controlled by the internal secretion of four glands, namely, that of the islands of Langerhans, this being opposed by the suprarenal gland, the thyroid gland, and the posterior lobe of the pituitary gland.

The islands of Langerhans.—The relation of the pancreas to the metabolism of sugar has been recognised ever since von Mering and Minkowski, in 1889, showed that complete removal of the gland caused glycosuria and death of the animal. If, in a dog, the remnant be $\frac{1}{4}$ th to $\frac{1}{10}$ th of the whole gland, mild diabetes occurs; if less than $\frac{1}{10}$ th, severe diabetes results (Allen). The pancreas is made up of two glands:—(1) the acinous portion, which secretes the pancreatic juice through the pancreatic duct. It has no action on the sugar metabolism, since if it is entirely destroyed as a result of ligaturing the duct and replaced by fibrous tissue the sugar metabolism is quite unaffected so long as the islands of Langerhans are intact. (2) The islands, first described by Langerhans in 1869, are now recognised as definite entities, forming about $\frac{1}{100}$ part of the whole pancreas, and having an abundant blood supply. They contain three kinds of cells, called alpha, beta and gamma cells, which contain granules in their protoplasm as in the case of the gland cells of other organs. The alpha cells form about $\frac{1}{3}$ rd, and the beta about $\frac{2}{3}$ rds of the islands, while the gamma cells are few in number. The granules in the alpha cells stain differently from those in the beta and gamma cells, and these again stain differently from those in the acinous portion. Hence, if the tissues are fresh, the three kinds of cells in the islands can easily be distinguished from each other. When the surviving islands of a partially depancreatized dog are overworked by excessive sugar or carbohydrate feeding, only the beta cells are affected. The granules gradually disappear and a vacuole appears (hydrops of the cell). This process may continue until the cell finally consists of a large vacuole, with the nucleus flattened against one side, whilst all the granules have disappeared. Finally the cell breaks up and disappears. If the process is continued long enough the island will consist of alpha and gamma cells alone, and will be much smaller than usual. These experiments prove that it is the beta cells which control the sugar metabolism. The action of the alpha and gamma cells is unknown. The internal secretion of the beta cells had never been isolated until 1922.

Banting, working with Best, succeeded in preparing an extract which had the power of lowering the blood sugar of a depancreatised dog, and of prolonging its life considerably. At first it was necessary to destroy the acinous portion of the pancreas by ligaturing the duct thirteen weeks before the extract was made, but now the extract is made from the fresh gland, and the toxic action of the trypsin is prevented.

Properties of Insulin.—The extract of the islands of Langerhans is called insulin. Its exact constitution is not yet known. It almost certainly contains a protein nucleus, since the purest preparations always give some of the tests for proteins. It forms salts with acids, such as hydrochloric acid.

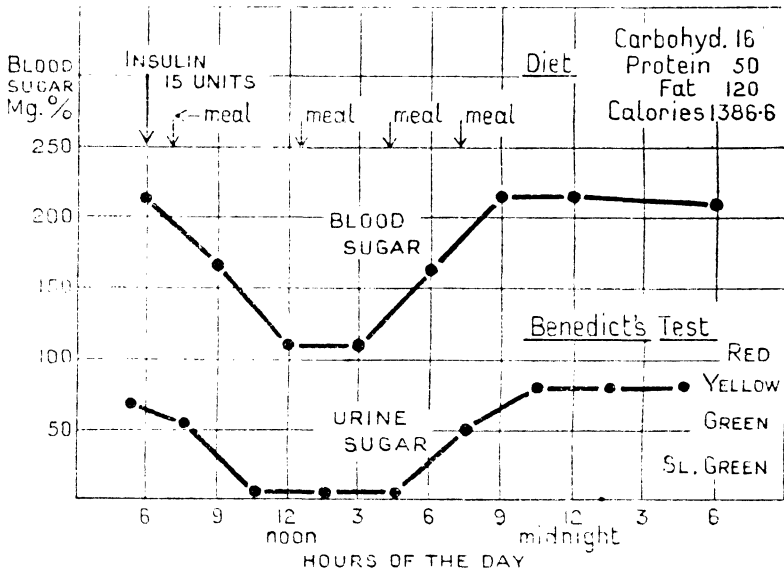

FIG. 10.—Figure showing the effect of a dose of insulin on the blood sugar and urine sugar of a diabetic patient.

The hydrochloride is a white powder, which is slightly deliquescent, and dissolves in acid and alkali, but is destroyed by the latter. It is also destroyed by pepsin and trypsin, and, therefore, cannot be absorbed from alimentary canal.

The presence of sufficient insulin in the body is necessary for the correct usage of dextrose. Without it the dextrose cannot be stored in the body, but appears in excess in the blood and urine. When insulin is present in sufficient amount, the blood sugar is normal; if too much insulin is present, the blood sugar is reduced in amount and there is no glycogen in the liver; if insufficient insulin is present, the blood sugar is increased in amount, so that sugar cannot be burnt, and the respiratory quotient falls to about 0.7. If enough insulin and dextrose are present, the respiratory quotient will be about 1.0, and the fat in the diet will be burnt correctly, so that no acetone

bodies appear in the urine. The precise way in which insulin acts is not yet understood, as it has no action on dextrose outside the body.

The potency of insulin is estimated by its power to lower the blood sugar of a healthy fasting rabbit or mouse to a certain level. The amount of insulin which lowers the blood sugar of a healthy fasting rabbit weighing about 2 kilograms to 45 mgm. per cent. in 2 hours is termed 2 units, and this represents about 0.2 mgm. of the pure product. All the insulin prepared in this country has been carefully tested under the supervision of the Medical Research Council. It is dissolved in acid solution, and is of such a strength that 1 c.c. contains 20 units (U. 20), or 40 units (U. 40, double strength). It is put up in rubber-capped bottles, and does not deteriorate even in hot climates.

If too big a dose of insulin is given to a rabbit, the blood sugar will fall below 45 mgm. per cent. and the animal may have convulsions and die. These symptoms can be relieved at once by the subcutaneous injection of 2 or 3 grammes of sugar, unless the dose of insulin has been very large. Adrenalin, 1 in 1000, 1 c.c. (M. xv), or pituitrin, 10 units (1 c.c.), will also relieve the symptoms at once, but it is advisable to give sugar afterwards. In human beings insulin acts in a similar manner, and if sufficient insulin is given the blood sugar is always lowered. A dose of 5 to 10 units will lower the blood sugar of a healthy fasting adult of about 65 kilos to about 50 mgm. per cent., but usually does not cause any symptoms of hypoglycæmia. Human beings, considering their much greater weight, are, therefore, much more sensitive to insulin than a rabbit.

When the blood sugar is raised, as in diabetes, the insulin causes a similar decrease in the blood sugar provided that a sufficient amount has been given. The extent to which the blood sugar is lowered varies in every patient and no definite law can be stated. The maximal decrease (Fig. 10) occurs about 3 to 6 hours after the dose, depending on the size of the dose of insulin, and may persist for about 10 hours, and after that the blood sugar begins to rise again. If the level of the blood sugar was above the threshold of the kidney for sugar the urine will contain sugar, but as soon as the blood sugar falls below the threshold the urine will not contain any sugar. If the urine is collected every 2 or 3 hours and tested for sugar, it is possible to determine whether the blood sugar has fallen below the threshold or not. If the blood sugar is lowered to about 50 mgm. per cent., there may be symptoms due to the hypoglycæmia; but there is no definite level at which all patients develop symptoms, since some patients may feel quite well at this level whereas others, especially those who have had a high blood sugar for a long time, may experience severe symptoms although the blood sugar is 90 mgm. per cent. or even 140 mgm. per cent. The mild symptoms due to hypoglycæmia are a feeling of inertia, profuse sweating, tremor of the hands, and abdominal pain resembling hunger pains; and sometimes mild delirium and tachycardia may be observed. Rather more severe symptoms are numbness of the hands, face and tongue, diplopia and difficulty in articulation. Severe symptoms are:—(1) A state of unconsciousness resembling a deep slumber from which the patient cannot be roused. (2) Fits which may resemble epileptic fits; these occur chiefly in young children and only rarely in adults. (3) A state of inco-ordination of the muscles resembling locomotor ataxia.

The mild symptoms are easily relieved by a little orange juice, tomato juice, or some of the ordinary food of the diabetic patient, provided that it is given as soon as the symptoms appear. The more severe symptoms are relieved at once if a sugar solution is drunk. If the patient is unable to swallow, adrenalin, 1 in 1000, 1 c.c. (III xv), or pituitrin, 10 units (1 c.c.) will usually relieve the symptoms at once, but some sugar, about half an ounce (25 g.) should be given as soon as the patient is able to swallow. If the patient does not respond to treatment, dextrose 5 per cent. in saline should be given intravenously or per rectum.

The suprarenal gland.—The internal secretion of the medulla of this gland, called adrenalin, has a definite action on the sugar metabolism. If it is injected subcutaneously an increase in the blood sugar occurs, and glycosuria may occur if the level of the blood sugar is above the threshold of the kidney. An increase in the blood sugar also occurs when the splanchnic nerves are stimulated, and if the floor of the fourth ventricle is punctured, provided that the suprarenal glands are intact. Fear and excitement may also cause hyperglycæmia and glycosuria, e.g., Macleod's football players. It acts as an antidote to the excessive action of insulin. The gradual destruction of the suprarenal in Addison's disease does not affect the level of the blood sugar, although an injection of adrenalin still increases the blood sugar in the usual manner.

The thyroid gland.—This has some influence on the sugar metabolism, since the sugar tolerance is lowered when the gland is active, as in exophthalmic goitre, or if too much thyroid extract is administered. When there is atrophy of the gland, as in myxœdema, the sugar tolerance is increased.

The posterior lobe of the pituitary gland.—The internal secretion of the gland has some influence on the sugar metabolism, since in Fröhlich's syndrome the sugar tolerance is much increased. Feeding with extract of the posterior lobe causes a decrease in the sugar tolerance. Although pituitrin has no direct action in raising the blood sugar, it acts as an antidote to the excessive action of insulin.

Morbid Anatomy.—The pancreas does not show any macroscopic changes. Microscopically it may show fibrosis around the islands of Langerhans (Opie). If the pancreas is fairly fresh, the finer changes, hydrops of the cells and absence of Bensley's specific granules, are present in nearly 100 per cent. of cases (Allen). Well-marked fibrosis and deposition of iron are seen in cases of bronzed diabetes, both in the liver and pancreas. Evidence of syphilis may be present; Warthin found it at autopsy in 13 out of 14 cases, but in my experience it is rarely seen during life, only 3 out of 60 exhibiting the Wassermann reaction. The heart is usually small, and occasionally shows the vegetations of infective endocarditis. The lungs may show the changes of broncho-pneumonia, lobar pneumonia or tuberculosis. If there have been nervous symptoms during life, there may be definite changes in the spinal cord, such as sclerosis of the posterior columns. There is no change in the sympathetic ganglia.

LIPÆMIA.—In severe and advanced cases of diabetes the blood contains an excess of fat, either fatty acids or cholesterol. On separation of the corpuscles the plasma or serum has a pearly white appearance; this is always a sign of the severity of the disease, but patients have occasionally made fair recoveries of sugar tolerance. The retinal vessels in lipæmia are

very striking objects. In the less severe cases, the arteries and veins have a salmon pink appearance throughout their course. In the more severe cases, the vessels at the periphery become creamy white in colour, although near the disk, they are still salmon pink. In the severe cases, the distinction between the arteries and veins is completely lost and the vessels resemble flat ribbons. The vision remains unaffected.

Symptoms.—The onset of the disease may be very acute and great thirst is complained of; the very day of onset of the thirst can often be discovered. Some of these cases die undiagnosed. Usually the onset of symptoms is insidious, with lassitude, loss of energy, or pruritus, thirst not being a prominent symptom. In the mild cases, especially among elderly people, the diagnosis is usually made either by accident or in the course of a routine examination. In severe cases, thirst is the most troublesome complaint, and this necessitates drinking a great deal of fluid and passing a great deal of urine. The pruritus also troubles the patient, especially as the usual situation for it is the penis in males and the vulva in females. Weakness is usually complained of, and sometimes a large appetite is a troublesome symptom. Constipation is usually present, and it dates from the onset of the thirst in the acute cases. The tongue does not present any changes in mild or treated cases, but in severe and untreated cases it is dry and red—the so-called “raw beef” tongue; this is only present when the patient is “desiccated,” as a result of great polyuria. There is always great loss of weight. In the severe cases, the volume of the urine may be 4, 6, 8 or even 10,000 c.c. per diem, but in the treated case it is usually less than 2000–3000 c.c. The specific gravity of the urine in the untreated case may be 1040 or 1050, depending on the amount of sugar in the urine.

Complications.—(a) *Coma*.—Formerly this was a frequent termination of the disease, but now it should only be seen in—1. The very acute and the undiagnosed cases. 2. The severe and untreated cases. 3. As a terminal event as a result of any acute infection. Out of 9 cases of coma, 7 showed definite signs of a severe disease, 1 became comatose 7 days after the onset of the thirst, and in 1 no cause for the coma was discovered (Graham). There are two main types, namely—(1) the hyperpnœa is well marked (air hunger), but the patient remains conscious until just before death; and (2) the hyperpnœa is not very obvious, but the patient becomes deeply unconscious a long time before death. More usually the patient shows a mixture of these two types. The blood pressure is low in both types, and the tension of the eyeball is very low. Constipation is always marked, and the contents of the intestines after death may be enormous.

(b) *Local infections*, such as boils and carbuncles, often occur, and the latter is often a fatal complication. Perforating ulcers of the feet occur in long-standing cases with signs of peripheral neuritis. Pigmentation of the skin, especially on the back of the hands, occurs in bronzed diabetes.

(c) *Gangrene* of a limb, usually a leg, often occurs in elderly people. It is due to the associated arterial condition, and not to the diabetic condition.

(d) *Pulmonary*.—Tuberculosis of the lungs is a common termination of the disease, and lobar and broncho-pneumonia are serious complications, as the patients pass rapidly into coma.

(e) *Renal*.—A trace of albumin is often present. Œdema may occur after

two days of starvation, or after the administration of much sodium bicarbonate. Casts may be present in very large numbers in coma.

(f) *Nervous system.*—The knee-jerks may be lost early, but they may return if treatment is successful. Numbness and paræsthesia may be present. Symptoms resembling those of tabes dorsalis and due to degeneration of the posterior columns may be present. The vibration sense is often diminished or even absent in the legs. The temperament of the patient often changes, partly as the result of dietetic deprivations.

(g) *Eyes.*—Cataract is an occasional complication, and retro-bulbar neuritis may occur. Diabetic retinitis closely resembles albuminuric retinitis and is very difficult to distinguish with the ophthalmoscope. Lipæmia retinalis has been already described (p. 409).

(h) *Sexual functions.*—These may be undisturbed in the early stages of the disease, but in the late stages the male is impotent. The female may become pregnant, in which case the disease usually becomes worse. The child is never a diabetic at birth.

Diagnosis.—If the urine is tested the presence of a reducing substance is readily detected, but the nature of the reducing substance is less easily determined.

Fehling's solution is still commonly used, but the limitations of the test should be recognised. Solutions A and B should be freshly mixed, and equal quantities of urine and reagent boiled separately, mixed and not reboiled. If sugar is present in more than 0.5 per cent., the red precipitate comes at once, if in less than 0.5 per cent., it may not appear for one or more minutes. Fehling's solution is also reduced by glycuronic acid, uric acid, and creatinine. These substances are rarely present in sufficient amounts to reduce the copper solution, but when the urine is very concentrated they may cause a slight reduction.

Benedict's qualitative solution (copper sulphate, 17.3 grammes; sodium citrate, 173 grammes; anhydrous sodium carbonate, 100 grammes; water to 1000 c.c.) is not reduced by these substances. It is much more reliable than Fehling's solution and should replace it. Five or three c.c. of Benedict's solution and 10 or 6 drops of urine are boiled together for 2 minutes, or put in a boiling water bath for 5 minutes. If much sugar is present the precipitate develops on boiling, but small amounts may not cause a reduction before 2 minutes. The test will show the presence of sugar in a concentration of 0.08 per cent.

Benedict's solution is reduced by dextrose, lævulose, lactose, pentose and homogentisic acid (alkaptonuria), and special tests are necessary to distinguish these. Dextrose is dextro-rotatory, ferments with yeast, and yields crystals of glucosazone. Lævulose is lævo-rotatory, ferments with yeast, yields crystals of glucosazone, and gives Seliwanow's test. Lactose is dextro-rotatory, does not ferment with yeast, and yields a lactosazone with difficulty. Pentose is dextro-rotatory or optically inactive, is not fermented by yeast, and gives Bial's test. Homogentisic acid (alkaptonuria) reduces Fehling's and Benedict's solution to a deep brown colour; the urine blackens on standing, reduces an ammoniacal solution of silver nitrate to a black precipitate, and gives a momentary deep blue colour with the addition of a drop of very dilute ferric chloride. It does not ferment with yeast and is optically inactive.

If dextrose is present, disease of the other ductless glands and cerebral

tumours should be excluded. The pigmentation of the skin of the body and of the backs of the hands, together with an enlarged liver (bronzed diabetes), should be looked for. Acute and chronic pancreatitis should be thought of before the diagnosis of a primary lesion of the islands of Langerhans is accepted. If small amounts of dextrose are present it is necessary to make a complete test of the sugar tolerance, with estimation of the blood sugar every quarter- or half-hour for 2 hours after a dose of sugar, in order to exclude the possibility of renal glycosuria (see p. 421).

TESTS FOR ACETONE BODIES.—*The ferric chloride test.*—Add the solution drop by drop until all the phosphates are precipitated. As soon as this occurs, a violet colour appears if aceto-acetic acid is present in the urine in any quantity. This is a test for aceto-acetic acid, which can be detected in watery solutions in a dilution of 1 in 100,000. In urine, however, the test is much less delicate, owing to the interference of the pigments in the urine. The presence of sodium salicylate in the urine may cause confusion, but the colour produced in this case is purple. The distinction can be made by boiling the urine with a little weak acetic acid, and repeating the test when the urine is cold. The aceto-acetic acid distils away, whereas the sodium salicylate is unaffected by the boiling. This possibility of confusion is avoided by always using Rothera's test.

Rothera's nitroprusside test.—Saturate the urine with ammonium sulphate crystals, add 2 c.c. of liquor ammoniæ fort., and then a few drops of a fresh solution of sodium nitroprusside. If a little aceto-acetic acid is present, the permanganate colour develops slowly; if a great deal, the colour develops instantaneously, and it is impossible to see through the mixture after 20 to 30 seconds. When the nitroprusside reaction is strongly positive, the urine should be diluted 1 in 5. If the colour still appears instantaneously and deepens rapidly there is a large amount of aceto-acetic acid present. Aceto-acetic acid can be detected in a dilution of 1 in 400,000, and acetone in a dilution of 1 in 10,000.

There is no colour test for β -oxybutyric acid, but it is always present when more than 2 grammes of aceto-acetic acid are present.

Prognosis.—This depends, as in the case of other diseases, on the severity of the attack, the time which has elapsed between the onset of the disease and the commencement of treatment, the skill of the medical adviser, the care with which the patient follows the directions given, and the complications which occur. The attack is more likely to be severe and rapidly fatal in young people, but quite mild cases are often seen. In elderly people mild attacks are the rule, but severe attacks also occur. The prognosis had been much improved by the new dietetic treatment introduced in 1915. But although the prospects of life for several years were much better than they had been, the outlook remained a gloomy one for the patient with a severe form of the disease. The introduction of insulin has greatly improved the chances of life of all patients with any form of diabetes, but especially in the case of those with the severe forms. How much longer these patients will live it is impossible at present to say, but probably for many years, provided no complications occur. Insulin has completely altered the prognosis in the case of pregnancy. The risks usually attendant on the pregnancy and puerperium constitute the chief danger.

Treatment.—Although the introduction of insulin has altered the

prognosis, it has not altered the principles of treatment which have been in use for the last ten years. Great attention has always been paid to diet, but under the stimulus of insulin much more attention is being devoted to it. The principles which govern treatment are :—(1) the blood sugar of the patient when fasting should be within the normal limits of 0·08 per cent. and 0·12 per cent., and should not rise above 0·19 per cent. at any time of the day. It follows from this that the urine should never contain any sugar. (2) The urine should contain either no aceto-acetic acid or a *mère* trace. (3) The patient should understand that a large portion of the reserve power of the islands of Langerhans has been lost, and that he must arrange his life so that the surviving islands of Langerhans are never overworked, *i.e.*, the insulin requirements should be as small as possible. Moderate restrictions of the carbohydrate may be sufficient to prevent glycosuria in the mild type of case which occurs among elderly people, but in the great majority of cases this is quite inadequate. Removal of carbohydrates from the diet without reduction of the fat and protein of the diet is a dangerous practice and has in the past precipitated the onset of coma. Treatment should be begun as soon as the diagnosis has been made. It is convenient to watch the output of sugar and acetone bodies for one day on an ordinary diet, but if the patient is seriously ill this should be omitted. The patient should be in bed.

In Allen's original plan the patient was starved until no sugar was excreted in the urine. Prolonged periods of starvation are no longer necessary, but a short one of one or two days is very useful, as it is often sufficient to lower the blood sugar to normal and it makes the patient much more amenable to the drastic reductions in the total amount of food allowed. If it is desired to avoid a period of fasting, the patient may be given at once a diet which is just sufficient to satisfy the basal needs of the body. The following calculations are necessary in order to do this accurately. The patient's weight and height are marked on the Boothby and Sandiford Nomograph (p. 399). The figure for the surface area of the body is noted. Example: Height, 63 inches; weight, 132 lb.; surface area, 1·62 square metres. The calories required for each square metre of body surface are found in the Aub-Du Bois table below, which in the case of a man aged 40 are found to be 1497.

AUB-DU BOIS TABLE. Caloric Requirement per Square Metre of Body Surface.

Age (years).	Calories per day.		Age (years).	Calories per day.	
	M.	F.		M.	F.
10-12	1236	1200	20-30	948	888
12-14	1200	1116	30-40	948	876
14-16	1104	1032	40-50	924	864
16-18	1032	960	50-60	900	840
18-20	984	912	60-70	876	816

M. = males. F. = females.

Calculate requirement in children according to weight. Up to -

22 lb.	27·5 cals. per lb.
22-33 lb.	25·0
33-44 lb.	25·0

An approximate result may be obtained by multiplying the patient's weight by 11.3, the error never being large. The diet must be correctly balanced, and the number of grammes of fat should equal the sum of twice the number of grammes of carbohydrates plus half the number of grammes of protein. This is best expressed by an equation $F=2C+\frac{1}{2}P$. The caloric value to be given—in this case, 1490—is then divided between the carbohydrate, protein and fat in the following way. For an adult, $\frac{1}{2}$ g. of protein per 1 lb. of body weight is allowed. In the sample case the allowance is 66 g. This figure multiplied by 4.1 (the caloric value of protein) gives 270 calories and leaves 1220 for division between the carbohydrate and fat. In order to prevent any ketosis, the balance between these two must be carefully struck. If the caloric value—1220—is divided by the arbitrary figure 30, the quotient is the amount of carbohydrate to be consumed per diem—in the sample 41. This figure multiplied by 4.1 (the caloric value of carbohydrate) gives 168 calories; 1220 minus 168 leaves 1052 calories for the fat, and this figure divided by 9.3 (the caloric value of fat) gives 114 for the grammes of fat. The diet is then prescribed as: carbohydrates (C), 41 g.; protein (P), 66 g.; fat (F), 114 g.; calories (Cals.), 1490. The total amount of calories is divided into four meals, of approximately the following amounts:—Breakfast: C, 13.5; P, 22; F, 38; Cals., 499. Midday: C, 9; P, 15; F, 25; Cals., 330. Tea: C, 5; P, 7.5; F, 12; Cals., 163. Evening: C, 13.5; P, 22; F, 38; Cals., 499. This is called the "Maintenance Diet." The behaviour of the blood and urine sugar is watched, and insulin is administered according to the principles discussed later (p. 416). If a fast has been given, it may be broken in many different ways, but the following plan, known as the ladder diet at St. Bartholomew's Hospital, is simple to carry out, and can be varied very easily (see p. 415).

If the blood sugar is normal when Diet 5 is reached the question of insulin should be considered. It is possible that insulin is not actually required, but a small dose, such as 5 units of insulin, will often greatly improve the clinical condition. After a few weeks or months the insulin can be discontinued and the progress watched. In the mild cases the diet can be increased by the addition of 1 or 2 ounces of bread and 4 ounces of milk. Extra protein and fat may also be given if necessary, in order to keep the body weight constant. The diet may then be set out as follows:—Carbohydrate 53 grammes, Protein 65, Fat 130 and Calories 1688. This amount of food may be sufficient to make thin and wasted patients gain weight, but if not extra protein and fat should be added in the proportion of 12 g. protein to 6 g. fat every 2 weeks until the weight does begin to increase. Very fat patients should continue to lose weight until a reasonable weight is attained. If the patient is intelligent enough he can be given a set of diet tables and allowed to choose his own diet. The tables of Harrison and Lawrence are very convenient, as the amount of carbohydrate, protein and fat in the various foods is set out in a convenient form.

If the patient is unintelligent, the diet should be carefully set out with a list of alternatives. A hospital patient is usually content with much less variety than in the case of the well-to-do.

It is important to arrange the diet so that there is a proper balance between the substances which cause a ketosis and those which prevent it.

THE LADDER DIET OF ST. BARTHOLOMEW'S HOSPITAL.

The sum of the ketogenic substances is called the aketogenic ratio, or the A.K. ratio. This ratio should be between 1.6 and 1.7. Pure carbohydrate is 100 per cent. antiketogenic; pure protein is 58 per cent. antiketogenic and 46 per cent. ketogenic; pure fat is 10 per cent. antiketogenic and 90 per cent. ketogenic. The A.K. ratio will be 1.6 when the fat is equal to the sugar of the diet multiplied by 2.16 + the protein of the diet multiplied by 0.635. This is written $F = 2.16 C + 0.635 P$, or more simply $F = 2 C + \frac{1}{2} P$. When the diet is correctly balanced, there should be no trace of aceto-acetic acid, as shown by the nitroprusside test. If, however, the reaction only develops slowly, the amount of aceto-acetic acid is insignificant and the diet may be considered as correctly balanced. The use of insulin has enabled the amount

of carbohydrate to be much less than the hypothetical values demanded by the above equation, and the A.K. ratio is important in children and when no insulin is being injected.

If the urine still contains sugar or if the fasting value of the blood sugar is above 200 mgm. per cent. when Diet 5 is reached, or the patient is on the maintenance diet, he requires insulin in order to allow him to rest the islands of Langerhans properly. The initial dose should be 5 or 10 units, and if after 3 days no change has taken place in the blood sugar the dose should be increased by 5 units at a time every third day until the dose is 20 units. The patient should be in bed and under proper supervision of trained nurses, and it is an advantage to have facilities for estimating the blood sugar. If this amount is not sufficient to lower the fasting value of the blood sugar to normal, 5 units of insulin should be given about 6 p.m. The evening dose should then be increased every third day by 4 units until it reaches 20 units. This amount of insulin is sufficient to lower the blood sugar to normal in the great majority of cases. In a few cases the insulin must be still further increased, but it should only be done if the patient is under very careful supervision. It is sufficient to estimate the blood sugar once or twice a week, provided that the patient is responding well. After the fasting value of the blood sugar has been reduced to normal it may be necessary to decrease the dose of insulin, and a careful watch should be kept for any symptoms of overdosage. The patient should be told to report any symptoms, and the nurses must know how to treat them, either with orange juice, or sugar, or adrenalin (see p. 409).

If it is not possible to estimate the blood sugar, treatment with insulin may be carried out provided that the urine is collected in 3-hourly periods and tested for sugar. So long as the blood sugar is above the threshold, *i.e.* above 180 mgm. per cent., the urine will contain sugar, but if the dose of insulin is adequate to lower the blood sugar below 180 mgm. per cent. the urine will not contain any sugar. It is then important to test each succeeding specimen, so as to be able to say when the blood sugar rises above 180 mgm. per cent. again. By testing the urine in this way the fasting value of the blood sugar may be lowered to below 180 mgm. per cent., but after that it is very difficult to say whether the fasting value of the blood sugar is normal or not, and it is essential that the blood sugar should be estimated.

When the blood sugar is normal the question of the increase in the diet must be considered. If the patient's weight is decreasing, he is not having enough food, and the protein and fat should be increased by about 100 calories at a time every week until the weight begins to increase slowly. If the weight is constant and the patient is not more than 10 per cent. underweight, the caloric value of the food is adequate. If the patient is gaining weight rapidly, the food is too much and should be decreased, but exercise may also cause a reduction in weight. If the patient insists on having more carbohydrate, it should be given, with the addition of 1 unit of insulin for each 2 grammes of sugar. In this case the insulin should be given about 30 minutes before the carbohydrate is taken, in order to prevent the blood sugar rising either too high or falling too low. It is not good practice to give 30 units of insulin with a large amount of carbohydrate, say 2 ounces of bread, because there is always the risk that the carbohydrate may not be absorbed and the patient may then suffer severely from hypoglycæmia. Active exercise may

cause hypoglycæmia, in which event extra carbohydrate should always be available.

The patient should understand the composition of his diet, and how to vary it.

FOOD VALUES

Table I. contains some of the carbohydrate-containing foods, and 5 grms. carbohydrate are contained in the following weights of the edible parts of vegetables, fruits and nuts. The vegetables are cooked, unless otherwise stated. Any one item, therefore, may be substituted for any other without risk of serious error.

TABLE I

A. VEGETABLES		FRUITS	
<i>Group 1—</i>		Apple	2 oz.
Asparagus	11 oz.	Apricot (fresh, with stone)	4 ..
Cabbage	13 ..	Banana	1 ..
Cauliflower	12 ..	Blackberries	3 $\frac{3}{4}$..
Celery (raw)	17 ..	Cherries (with stone)	3 ..
Cucumber (raw)	9 $\frac{3}{4}$..	Damsons (with stone)	4 ..
French Beans	13 ..	Gooseberries (raw ripe)	3 ..
Lettuce	25 (unripe, stewed)	11 ..
Mustard and Cress	35 ..	Greengage (with stone)	2 $\frac{3}{4}$..
Rhubarb	30 ..	Grape Fruit	3 ..
Radishes (raw)	11 $\frac{1}{2}$..	Grapes	1 $\frac{3}{4}$..
Sea kale	13 $\frac{1}{2}$..	Melon	6 $\frac{1}{2}$..
Spinach	13 ..	Oranges	2 $\frac{1}{2}$..
<i>Group 2—</i>		Peaches (with stone)	3 ..
Brussels Sprouts	6 oz.	Pears	2 $\frac{1}{2}$..
Jerusalem Artichokes	5 ..	Plums (with stone)	2 ..
Leeks	4 $\frac{3}{4}$..	Raspberries	6 $\frac{1}{2}$..
Marrow	8 ..	Red or Black Currants	4 $\frac{1}{2}$..
Tomatoes	7 $\frac{1}{2}$..	Strawberries	4 ..
Turnips	5 ..	<i>C. NUTS</i>	
<i>Group 3—</i>		Almonds	1 oz.
Beetroot	2 $\frac{1}{2}$ oz.	Brazil Nuts	2 $\frac{3}{4}$..
Carrots	3 $\frac{1}{2}$..	Chestnuts	3 ..
Onions	3 ..	Hazel Nuts	1 $\frac{1}{2}$..
Parsnips	1 $\frac{1}{2}$..	Walnuts	1 $\frac{1}{2}$..
Peas, Green	1 $\frac{1}{2}$..	<i>D. STARCHY FOODS</i>	
Potatoes	1 ..	Milk	3 $\frac{1}{2}$ oz.
		Bread	$\frac{1}{2}$..
		Dry Oatmeal	$\frac{1}{4}$..
		Rice	$\frac{1}{2}$..

After R. D. Lawrence, *The Diabetic Life* (J. and A. Churchill).

TABLE II.—PROTEIN AND FAT

The following articles of food contain approximately 6.5 to 7.0 grms. protein, and 6.5 to 7.0 grms. fat, and may be substituted for each other without causing serious error.

oz. Beef.	1 oz. Rabbit, with the addition of $\frac{1}{4}$ oz. Butter.
.. Mutton.	.. White Fish, with the addition of $\frac{1}{4}$ oz. Butter.
.. Lamb.	.. Ham.
.. Veal.	.. Cheese.
Egg.	1 $\frac{1}{2}$.. Bacon, but $\frac{3}{4}$ oz. Butter should be deducted from the Butter ration.
oz. Sardines.	5 .. Cream + 1 oz. Butter.
.. Salt Herring	
.. Salmon.	
.. Chicken with the addition of $\frac{1}{4}$ oz. Butter.	

1 gm. Protein	4.1 Calories.	6.25 grms. Protein	1 gm. Nitrogen.
1 .. Carbohydrate	4.1 ..	1 kilogram	2.2 lb.
1 .. Fat	9.3 ..	30 grms. or cubic centi	
1 .. Alcohol	7 ..	metres (c.c.)	1 oz.

A patient at rest requires 25 calories per kilo body-weight per 24 hours, approximately 1 calorie per kilo per hour.

Diabetic foods should only be eaten when their exact composition is stated. Some of the so-called diabetic foods contain over 40 per cent. of starch, so that only a small portion of the starch of the bread has been removed. The diabetic bread should be eaten as a part of the protein and fat ration, and never as an addition. Diabetic jellies and jams all contain about 20 per cent. of glycerine, which is burnt as sugar and must, therefore, be included under the carbohydrate ration.

The general health of the patient should be treated. Any sources of infection, such as pyorrhœa, cholecystitis, boils, etc., reduce the sugar tolerance considerably. The possibility of syphilis should also be inquired into, and, if necessary, treated.

The after-treatment is very important. The patient should be taught as much as is possible about the disease and diet, for if he understands the principles concerned, he is much more likely to carry out the treatment correctly. He should also be taught to test the urine with Benedict's solution. If no insulin is taken the urine passed after the evening meal should be tested, but if insulin is used the urine immediately before the injection in the morning or evening should be tested.

Medicinal treatment.—Many preparations of the pancreas or of herbs which can be taken by mouth are extensively advertised. With one exception they are all valueless as well as being expensive. Synthalin, 40 mgms., with decholin, 25 mgms., given for 3 days at a time with one day's rest, has a definite though slight action on the glycosuria and glycæmia in many cases. It has the great disadvantage that it often causes toxic effects, such as dyspepsia, vomiting and jaundice. It should not be recommended unless the patient refuses insulin. Purgatives are of great importance, and the necessity of an efficient daily evacuation should be insisted on. Ext. aloes, gr. iv, ext. nuc. vom., gr. $\frac{1}{4}$, in pill form, one to two at night; inf. of senna pods, ten to thirty; phenolphthalein gr. ii iv or more in liquid paraffin 5i b.d.s., are the most efficacious; salines, together with tinct. jalapæ co. 5ss,

should only be used in emergencies. General tonics which improve the health may be used. Opium used to be of assistance in the late stages of the disease, but should not be required nowadays.

Coma.—This requires prompt and energetic treatment with large doses of insulin. The patient is sometimes very cold and collapsed, and he should be made warm as soon as possible, by means of a hot air bath, or, if this is not available, by hot water bottles, as in the treatment of surgical shock. The blood sugar is usually high, over 300 mg. per cent., and it is safe to give 30 to 50 units of insulin as soon as the diagnosis is made without waiting for a blood-sugar determination. If it is not possible to estimate the blood sugar, a dose of 50 grammes (2 ounces) of dextrose should be given by mouth or by an œsophageal tube, and 50 to 75 units of insulin. If there are no signs of returning consciousness in 3 hours, another 25 units of insulin, together with 25 grammes (1 ounce) of dextrose in solution, should be given. The urine should be collected every 3 hours, by catheter if necessary, and tested for sugar. The urine for the first 3 hours after insulin is certain to contain sugar, and if the urine for the 4th to 6th hours contains sugar, it is safe to give 30 to 50 units of insulin. If, however, the urine for the 4th to 6th hours does not contain sugar, it is dangerous to give any more insulin, unless sugar, in the proportion of 2 grammes to 1 unit of insulin is given by the mouth or intravenously at the same time. If there is any doubt as to whether the patient is recovering, this latter procedure should always be followed. If the condition, however, is improving no insulin should be given until sugar reappears in the urine. Water in as large amounts as is possible, either by mouth or by nasal catheter, should be given; at least 10 ounces each hour for some 6 hours. If the patient is vomiting and cannot retain fluid, it is necessary to give saline intravenously, which may have to be repeated every 4 hours. An estimation of the hæmoglobin should be made at intervals, in order to determine whether sufficient fluid is being given or not. Two ounces of castor oil should be given with the first drink, as these patients are nearly always very constipated. In coma the alkali reserve is always much reduced, and sodium bicarbonate is of assistance, although the enormous doses which were administered before the discovery of insulin should not be given. A dose of 12 grammes (3 drms.) is sufficient, and no advantage is to be gained by giving a bigger dose. After the patient has been conscious for about 2 days, a diabetic diet should be given.

Every patient in coma should be examined most carefully each day, in order to determine whether any other disease is present. In 7 out of 9 cases admitted to St. Bartholomew's Hospital in the first year of insulin treatment, an acute infection, e.g., acute otitis media, parotitis, or gangrene of the lung, was present. The appropriate treatment should be instituted as soon as possible.

Acute infections, such as influenza, usually cause a considerable diminution of the sugar tolerance. If the infection is of mild degree, it may be sufficient to increase the dosage of insulin by 2 or 4 units for some days. If, however, the infection is of severe degree, it is important that the condition should be adequately treated, so as to prevent (1) any danger to life, and (2) any permanent diminution of the sugar tolerance. The same procedure should be adopted as in the treatment of coma (Fig. 11), but the dose of insulin should be much smaller, unless the patient is very ill. Provided the urine is collected

in 3 hourly periods and tested for sugar, a sufficient dose of insulin may be given with safety, and thus reduce the ill-effects of the infection as much as possible.

Surgical operations were always contra-indicated before insulin was known, but they may now be carried out, provided certain precautions are observed. The patient's blood sugar should be reduced to normal, provided that there is time to achieve this. Gas and oxygen, local or spinal anæsthetics cause no ill-effects. Neither ether nor chloroform should ever be given alone, but the former may be given with gas and oxygen if deep anæsthesia is required, but as little as possible should be used. Fifty grammes (2 oz.) of sugar, together with 25 units of insulin, should be given about 2 hours before the operation, in order to have plenty of sugar and insulin in the body at the time of operation. After the operation the appropriate diet for the surgical disease, together with adequate amounts of insulin, should be given for the first few days, but as soon as possible the usual diabetic diet should be given and the blood sugar controlled again. If pregnancy occurs it should not be terminated unless there are other complications.

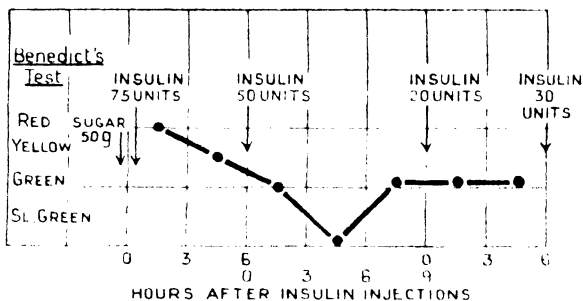

FIG. 11.— Figure showing how an adequate dose of insulin can be arrived at by testing the urine in a patient in diabetic coma.

LÆVULOSURIA is a sign of some incompetence of the liver and should direct attention to that organ. Slight reduction of carbohydrates and of fruits is usually sufficient to check it.

LACTOSURIA occurs (1) during lactation, (2) when suckling suddenly ceases, and (3) in breast-fed infants with enteritis.

PENTOSURIA is a rare occurrence. The majority of the patients are Jews. Of 7 cases, 3 were Jews, 2 Greeks, and 2 English (Cambridge).

RENAL GLYCOSURIA

This is an uncommon condition which is apt to occur in several members of a family. Although the blood sugar lies within normal limits, dextrose may be present in the urine either throughout the day or only after a carbohydrate meal. The sugar is usually small in amount, i.e., less than 10 grammes per diem, but several cases are reported in which 20 to 30 grammes were excreted in the day. The amount of sugar in the diet has little

influence on the total sugar excretion. The diagnosis should only be made after a series of observations. A complete test of the sugar tolerance with doses of 25 to 50 grammes of sugar should be made. Estimations of the blood sugar should be made at intervals of half an hour for 2 to 3 hours after the dose of sugar, and the amount of sugar excreted in the urine should be estimated. If sugar is present in the urine, although the blood sugar does not rise above 180 mgm. per cent. at the end of 30 minutes and has returned to the normal level after 2 hours, the patient probably belongs to the renal glycosuria class.

The prognosis is good, and no treatment is required once a differential diagnosis is made. It is wiser to treat all doubtful cases with moderate restriction of the carbohydrate ration (100 grms.), and to repeat the sugar tolerance test in 1 to 3 months' time. Very little harm can be done by this procedure, while much damage can be done if a case of true diabetes is treated with no dietetic restrictions (Salomon, Graham).

GOUT

A disease in which there is a disturbance of the purin metabolism and an increase of uric acid in the blood. The clinical sign is an attack of acute arthritis with a deposition of sodium biurate in and about the joints.

Ætiology.—*Predisposing causes.*—Gout is much commoner among certain races, e.g. the English and German. It is practically unknown among native races. It does not follow, however, that this is a racial peculiarity. It is much commoner in temperate than in tropical climates, but it is unlikely that the climate plays any part in the causation of the disease. The evidence in favour of gout being an hereditary disease is very strong, as a history of a gouty ancestry can be obtained in 50 to 80 per cent. of the cases. A history of gout in the family was obtained in 75 per cent. of well-to-do patients and in 50 per cent. of hospital patients (A. B. Garrod). This evidence suggests that the disease is chiefly hereditary but may be acquired. It is not the disease which is inherited, but only the predisposition to it, and the disease may lie latent until it is evoked by other causes (Llewellyn). It is a disease of middle life—between the ages of 35 and 50—but it may occur much younger, even in schoolboys who have a strong hereditary taint. The malady is very much more common in men than in women. Women form only 5 to 20 per cent. of the patients in most statistical tables.

Exciting causes.—Food plays a part in the causation of the disease, but it is rather the quantity than the quality which matters. Meat and the purin bodies in tea, etc., probably have little effect, but sweetbreads may be actively harmful. Spirits have little effect, and gout is almost unknown in Scotland. Beer is much more potent and is probably partly responsible for the prevalence of gout in England and Germany. The strong wines like port and sherry, and the red wines such as Burgundy and claret, are also probably responsible for much gout among the well-to-do classes, and champagne has a bad reputation. The light white wines like Graves and hock are less evil. Gout was formerly very common among lead workers in England, and it seems to be a concomitant cause. Trauma

plays a great part in the causation of the acute attack. The big toe may be affected so frequently because of the pressure of the boot. An injured joint may be the seat of the first attack of gout. Syringing the ear of a gouty patient for cerumen was followed by an acute attack in the external auditory meatus (A. E. Garrod). Local sources of infection are very common among gouty patients, *e.g.* septic gums and tonsils. These used to be called gouty manifestations, but Llewellyn thinks that they may be responsible for causing the attack of gout.

Physiology and Pathology.—The fact that sodium biurate was deposited in and around the joints suggested that uric acid played an essential part in the causation of gout. After A. B. Garrod had demonstrated by means of his thread test that the blood of gouty patients contained uric acid in abnormal quantities the hypothesis seemed to be proved. The problem is, however, not so simple as was thought at first.

The uric acid which is excreted in the urine of healthy people on an ordinary mixed diet comes from two sources, exogenous and endogenous. When all the exogenous sources of uric acid, *e.g.* meat, fish, sweetbread, tea and coffee, etc., are removed from the diet the output sinks to a level of 0.5 to 0.7 gramme per day. This amount is fairly constant for each individual. If all proteins are removed from the diet, the endogenous uric acid output falls to a lower level than before (Folin). The removal of carbohydrates and a reduction of the caloric value of the diet also cause a decrease in the endogenous uric acid output to the lower level (Graham and Poulton). The endogenous uric acid output is believed to come from the breakdown of the cell nuclei of the body, *i.e.* wear-and-tear, but it can also be synthesised from histidin and arginin (Hopkins and Ackroyd). When the exogenous purins are eaten, or when uric acid is injected, there is an increase in the uric acid output, but the whole of the uric acid is not excreted in one day. If cinchophen is given at the same time, the excretion-rate of the uric acid is increased.

The blood always contains uric acid, and the limits of normal variation in health are 1 to 3 mgms. per cent. The total uric acid in the blood of a man weighing 10 st. 3 lb. or 65 kilos would be 0.05 to 0.15 gramme, assuming that the blood constitutes $\frac{1}{15}$ th of the body-weight, *i.e.* 5000 c.c.

In cases of gout there is usually a considerable increase in the amount of uric acid in the blood. Before an attack the blood may contain 4 to 6 mgms. of uric acid per cent., though occasionally between the attacks there may be only a slight increase. The uric acid may also be increased in some people who have never had gout; thus, in leukæmia, where there is a great destruction of leucocytes, and in severe cases of nephritis. The increase in the uric acid in the blood is, therefore, not pathognomonic of gout, although it is extremely suggestive of it.

In gout the output of uric acid varies widely. It may be quite small in amount, less than 0.20 gramme per day, or it may be equal to that excreted by healthy people. Before the attack of gout it is usually very small in amount, but the paroxysm always causes a great increase in the output for a few days only. When purin bodies are eaten by a gouty patient, or if uric acid is injected, there is great delay in the excretion of uric acid. If cinchophen is given at the same time, the uric acid is excreted much more quickly.

The diminution in the uric acid output may be due to an increased destruction in the body or to its retention by the kidneys. There is no evidence of increased destruction in the body, as the blood of a patient before an attack may contain 4 to 6 mgms. of uric acid per cent. This suggests that the uric acid is retained by the kidneys. When cincophen is given to a patient whose blood contains 4 to 5 mgms. per cent. uric acid there is a great increase in the uric acid output and a decrease in the uric acid in the blood (Folin and Lyman). The "extra" uric acid excreted in 6 days (Fig. 12) was 1.9 grammes, while the blood uric acid decreased from 4.5 mgms. to 2.9 mgms. per cent. The "extra" uric acid must come from

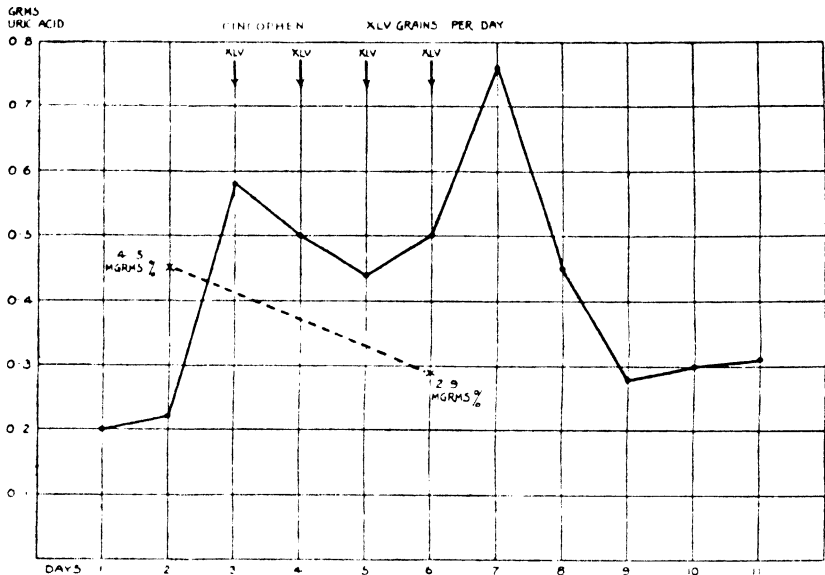

FIG. 12. Figure showing the increase in the output of uric acid in the urine and the decrease in the uric acid in the blood after cincophen.

the uric acid in the body fluids, as the blood does not contain enough uric acid (Graham) (Fig. 12).

The evidence points to the view that although gout cannot exist in the absence of excess of uric acid in the blood yet uric acid is not the cause of gout.

The essential change is the deposition of uric acid as sodium biurate in the joints. The sodium biurate appears to be plastered over the surface of the cartilage, but on microscopical examination it is seen that there is a layer of cartilage over the deposit, which is always interstitial. The deposits may be quite small or enormous. In many cases the structure of the bones is destroyed and replaced by sodium biurate. The ligaments, tendon sheaths and bursæ are also infiltrated. The big toe joints may contain sodium biurate, although the patient has never had an acute attack

of gout. The skin covering a tophaceous deposit may ulcerate and break down, and small masses of sodium biurate may be discharged (*chalky gout*).

Tophi.—Sodium biurate is also deposited in the cartilage of the ear, especially in the outer margin of the pinna. The tophi appear as white nodules, and uric acid crystals can be recovered from them, which also give the murexide test and a blue colour with Folin's phospho-tungstic reagent.

The kidneys.—An uratic deposit may occur in the pyramids. Norman Moore found it in 12 out of 80 cases. Well-marked changes of chronic interstitial nephritis are often found.

Symptoms.—The earliest sign of gout is often the deposition of sodium biurate in the cartilage of the ear (*tophus*). This stage usually passes unnoticed, but is sometimes accompanied by an intolerable itching or tenderness.

Acute gout.—The first attack of "classical" gout usually occurs at night. There may have been a few preliminary symptoms, such as dyspepsia, slight pain in the hands, and irritability of temper, but the patient goes to bed feeling well. "The patient suddenly wakes with pain, more or less intense, in the ball of one great toe, frequently accompanied with a slight shivering; the pain in the toe gradually increases and is attended with a sensation of burning, throbbing, together with great tension and stiffness; heat of skin and other symptoms of febrile disturbance usually follow the shivering, accompanied with a considerable degree of restlessness" (A. B. Garrod). The temperature is raised to 101° or 102° F., but after a few hours the patient begins to sweat and finally falls asleep. "In the morning the toe is swollen, the skin shiny, tense and dark red, and the whole joint is extremely painful" (A. B. Garrod). Usually the acute pain lessens in the daytime, but returns with great violence in the night hours. The temperature remains high and the temper of the patient is irascible in the extreme. The attack may last many days or pass away in two days. When the attack is ceasing "the inflamed joint becomes less tense and swollen, and pitting is readily produced on pressure" (A. B. Garrod). The attack may spread from the great toe to the other joints of the tarsus or to other joints of the body. The first joint of the big toe is most commonly affected. The ankles, knees and small joints of the hand and wrists are next in the order of frequency.

During the attack there may be a considerable degree of leucocytosis, 20,000 to 25,000, and all but 2000 to 3000 are polymorpho-nuclear cells, as the lymphocytes and other cells are unaltered by gout. The uric acid output, which was low before, is greatly increased for a few days. Sodium biurate is deposited in the cartilage of the joint and head of the bone, but the swelling and stiffness may eventually disappear completely. The acute attack may be complicated by a severe gastro-intestinal disturbance which may be fatal. There may be other symptoms, such as dyspnœa, delirium and coma, but these are probably due to a coincident uræmia. Phlebitis of the veins of the limb may be a complication of an acute attack.

After the attack, whether as the result of illness or as a consequence of the simple living which the patient has endured, the general health of the patient is much improved. The attack usually follows in the spring and autumn. The second attack may follow at once, or may be delayed for many years.

Chronic gout.—After several attacks the joint does not recover completely.

The deposits of urates occur in the ligament and capsule, as well as in the articular cartilages and bones. The joint, therefore, becomes swollen and irregular in its shape. The urate is especially deposited in the bursæ about the joints. In the advanced stages the skin over the uratic deposits breaks down and masses of chalky material are extruded, and the wounds heal with difficulty. The general health of the patient suffers after several attacks and does not recover completely. Dyspepsia is complained of, and the patient may show signs of high blood-pressure and arterial disease. The urine is increased in amount, and may contain albumin and casts.

Irregular gout.—Almost any symptom or physical sign which occurred in a person who was of a gouty disposition was formerly ascribed to gout. Cutaneous eruptions, such as eczema, gastro-intestinal disorders, cardiovascular symptoms and pericarditis, headache, migraine and neuralgia, were all thought to be gouty. A gouty patient may develop any of these diseases, but the belief that there is a general type due to gout is now regarded as unfounded. The urine is usually acid, and on cooling often deposits uric acid crystals. This does not mean that there is an excess of uric acid in the urine, but that the urine is too acid to keep the uric acid in solution. On heating the urine the urates are re-dissolved. Gouty persons may suffer from calculi. Glycosuria occurs in some cases, but usually responds readily to treatment. Albuminuria and casts are present when the kidneys are also affected. Elderly persons often suffer from chronic bronchitis. Gout has been accused of rendering patients more disposed to iritis, retinitis and glaucoma, but there is no evidence that the disease of the eye is in any way connected with gout.

Diagnosis.—The diagnosis in a case of classical gout, with recurring attacks of arthritis in the toe or tarsus, is easy, especially if the patient comes of a gouty stock or indulges in good food and drink. The presence of tophi is proof positive that the patient is a subject of gout. Tophi must be distinguished from Woolner's tip, fibroid nodules and sebaceous cysts, and in cases of doubt an examination should be made for the crystals of sodium biurate with the microscope, and for uric acid with the murexide test or Folin's phospho-tungstic reagent. The blood should be examined for uric acid in all cases of doubt, and if more than 3 mgms. per cent. are found the case is probably one of gout. It must be remembered, however, that the uric acid in the blood is increased in cases of chronic interstitial nephritis. While it is certain that gout does not occur in the absence of an increase of uric acid in the blood, the presence of excess of uric acid in the blood does not exclude the presence of other diseases.

Classical gout is much less common than it was, and the modern tendency is to overlook the disease. In the severe cases of gout in which the joints are severely damaged, the X-ray appearances are very striking (Fig. 13). The negative shows dark areas where the sodium biurate is deposited in large amounts and replaces bone or cartilage, since sodium biurate is not opaque, like the calcium ion. In the less severe cases there may be—(1) tipping at the articular margins; (2) a localised atrophy of the bone; (3) a narrowing of the joint space. These changes occur in other kinds of arthritis and are in no way characteristic of gouty arthritis (Llewellyn).

Prognosis.—If a patient has once had an attack of gout he will always be liable to another attack, unless he alters his way of living. The frequency

FIG. 13.—Line drawing from a radiogram showing the changes which take place in the bones due to the deposition of sodium biurate.

and severity of the attacks can be modified by treatment. The prospects of long life depend upon the state of the heart, arteries and kidneys.

Treatment.—*Dietetic.*—In perhaps no other disease have a greater number of dietetic fads been recommended. The total quantity of the food should be kept within reasonable limits, and civic dinners should be avoided. The meals should be simple but attractive. There is no difference between the different kinds of meat, except that for those who have dyspepsia chicken is more easily tolerated than beef and mutton. There is no need to deprive the patient of sugar, which is a common fad, or of starchy food, but they should be eaten in moderation. The same is true of fat. Some gouty persons are much too stout, and a reduction of weight is beneficial. The actively harmful foods are those which contain purins, such as sweetbreads, liver, kidney and brain. They should never be eaten, as the uric acid which they contain is much more slowly excreted than by a healthy patient. Attacks of gout have followed very quickly after eating sweetbreads and after the administration of purins for experimental purposes. The fruits and vegetables which contain an excess of oxalates, *i.e.* strawberries, rhubarb, spinach and asparagus, should be forbidden if oxaluria is present.

Heavy beers, strong wines like port and sherry, and also champagne, should be forbidden for gouty patients. The white wines, like Graves and hock, may be allowed in moderation if especially desired. If drunk in moderate amount whisky is probably the least harmful beverage. Mineral waters may be of considerable benefit to gouty persons. Their mode of action is uncertain, but is probably due not so much to the ingredients of the waters as to the amount of water drunk, the simple and restricted diet, and the regular and supervised life which the patient leads at a spa. Hot baths and douches are of assistance in aiding the recovery of stiff joints. The waters of Buxton and Bath in England, Vichy, Aix-les-Bains and Contrexeville in France, Wildbad and Homburg in Germany, Carlsbad and Marienbad in Czecho-Slovakia, and Saratoga, Bedford and White Sulphur in America, are the best known.

Local.—During the acute attack the joint should be covered with cotton-wool, placed on a pillow, and the bedclothes raised by means of a cradle. Hot fomentations or lotio plumbi c. opio may be applied.

Internal.—The treatment should be started with a purgative, and calomel is recommended. Colchicum is specific for the acute attacks. The pain is usually relieved quite quickly, and the redness of the skin and swelling of the joint subside. Fifteen to 30 minims of the tincture in an alkaline mixture should be given every 4 hours. The drug may cause vomiting or purgation, and its action must be carefully watched. Its mode of action is quite unknown, and it is of no value in averting an attack. Cincophen (Trade names: atophan, agotan, phenoquin, quinophan) is useless in relieving the pain of an acute attack, but it is most useful in averting attacks. It is given in tablet form, gr. xv three times a day for 1, 2 or 3 days consecutively in each week and should never be given continuously. It increases the output of uric acid in the urine and decreases the amount of uric acid in the blood, and thus prevents the continuous accumulation of uric acid in the body. The drug may, however, produce unpleasant symptoms, such as urticaria, dyspepsia and jaundice. The complication of jaundice may be a very serious matter, for acute yellow atrophy of the liver may develop and death

ensue. These toxic effects have usually, but not always, occurred: (1) when the drug has been given continuously, *i.e.*, without an intermission of 4 to 5 days between the courses; and (2) when its administration has been continued after minor symptoms of toxic action have appeared. The results of the treatment of undoubted cases of gout with cincophen are so good that its toxic action is most unfortunate. It would seem that its use should be restricted to the treatment of gout, and only given in short courses each week and discontinued at the first indication of intolerance. Further, as soon as the acute joint condition has passed, the dosage should be reduced to 10 grs. twice a day, one day each week for an indefinite time. Aspirin and sodium salicylate have a similar action to cincophen, but in order to obtain a good excretion of uric acid in the urine 100 to 150 grs. per diem of both is necessary. This dosage is large enough to cause minor effects of salicylism, whereas if cincophen is tolerated, it causes no ill-effects at all.

The general health of the patient must be attended to and all causes of sepsis should be removed. Radiant heat and massage are very useful for restoring the movements of a crippled joint.

OBESITY

Obesity is a condition in which there is an excessive amount of body fat.

Ætiology.—Certain races are more prone to become fat than others, *e.g.* the Dutch, South Germans, South Italians, Maltese, Hebrews, the natives of India and Ceylon, and some African races. A clear history of heredity was obtained by Fletcher in 60 per cent. of his cases. Obesity may develop at almost any age, but it is more likely to occur at certain ages: in babies, in children at puberty, in men after the age of 40, and in women during pregnancy or after the menopause. It is commoner among females than males.

Pathology.—The deposit of fat indicates that the caloric value of the diet is in excess of the individual's needs. This may be due to the large amount of food which is eaten, or to a small energy consumption in the body. Some fat people have a very large appetite and eat much more than is necessary to satisfy their energy requirements. The amount of exercise which is taken has a great influence on the amount of fat which is deposited. Thus, a patient who is lying in bed will gain in weight on a diet which contains much less caloric value than that which he eats when he is up and about. Although many cases of obesity are easily explained on the above grounds, there are many instances which cannot be explained so simply.

The investigations of the basal metabolism help us to understand many of these cases. The amount of oxygen which is burnt depends on the state of the patient. More combustion of oxygen takes place when the patient is taking exercise than when he is at rest, and when he has a meal than after a short fast. The metabolism of the resting, fasting individual is termed the basal metabolism. This is expressed in cubic centimetres of oxygen per minute per square metre of body surface. The basal metabolism is lower for adults than for children, and gradually decreases with each decade. It is lower for females than males. The basal metabolism can be altered by pro-

longed undernutrition and by the influence of the ductless glands. One of the results of underfeeding is a lowering of the basal metabolism, but the oxygen consumption of such a patient during exercise is unaltered. The action of the thyroid gland on the basal metabolism has been carefully studied, as there are two clinical conditions in which the thyroid plays an important part, namely, (1) in hypothyroidism, and (2) hyperthyroidism. In the first, the patients, among other symptoms, tend to increase in weight, and the basal metabolism in these cases is much lower than usual. In the second, one of the prominent complications is the rapid loss of weight which occurs, and the basal metabolism is much increased in these cases, and can be increased by giving thyroid extract and decreased by removal of large portions of the gland. When the basal metabolism is low, it is clear that the patient will tend to get fat, although he is eating less food than a patient whose basal metabolism is high. These experiments help us to understand many cases of obesity.

The action of the other ductless glands is not so well understood. When the posterior lobe of the pituitary gland is damaged by a tumour, considerable changes take place in the metabolism. The patients grow fat, and the fat is deposited in the characteristic feminine situations, i.e. the breasts and hips in male and female patients (Fröhlich's syndrome). When the posterior lobe is removed in dogs there is an increase in the weight of the animal (Cushing).

The sex glands have a considerable influence on the metabolism. When the glands develop at puberty there may be an increase or decrease in the fatty deposits. The female lays down fat around the breasts and hips, and assumes the characteristic feminine form. Removal of the testicles, as in eunuchs, usually causes an increase in the body-weight. During a pregnancy women often grow stout long before they have to restrict their normal activities, while after the pregnancy is terminated, the patient loses weight and recovers her figure. At the menopause many women tend to become stout.

In obesity the fat is deposited in the subcutaneous tissues, the great omentum, mesentery, and around all the organs, such as the heart and kidneys.

Symptoms.—The presence of large deposits of fat limits the activities of the patients and destroys their good looks. Many of the patients feel well, but some complain of difficulty in moving about, because of their great bulk. Others complain of shortness of breath on the least exertion. Some of the patients are anæmic. Eczema may occur on those parts of the skin which touch each other.

Treatment. *Dietetic.*—If the patient has only gained a little weight, moderate restriction of the carbohydrate and fat of the diet, together with an increase of exercise, may be sufficient. This is the basis of the well-known Banting cure. When the obesity is considerable, more drastic treatment is necessary if the patient really wishes to lose weight. It is a good plan to start the treatment with a fast day, when the patient should stay in bed. Tea and coffee, with milk and sugar, and gravy soups may be taken in any quantity. The fast day will often cause an initial drop of 1 or 2 lb. in weight and also a reduction in the size of the patient's appetite. The fast day should be repeated once a week, and after a few times the patient need not stay in bed.

The three components of the diet, i.e. fat, carbohydrate, and protein,

should be reduced in different proportions. The fat should be reduced as much as possible, because it has a very high caloric value and the patient has already an excess of fat in his body. Butter, cream, the fat of meat, and especially that of ham and bacon, should be avoided. Chicken is better than mutton or beef, as it contains less fat, while white fish contains no fat. The carbohydrates should be considerably reduced, but this must be done cautiously; for many patients are made miserable, complaining of lassitude and extreme hunger. This is probably due to the blood sugar being too low, since these symptoms occur as a result of an overdose of insulin (pp. 408, 409). The protein should be reduced least of all, for its combustion causes an increase in the metabolism of the body—the specific dynamic action of proteins. The total caloric value of the diet may have to be reduced to 1500, 1000 or even 500 calories before the patient begins to lose weight. The weight should not be decreased too rapidly. A decrease of 1 to 2 lb. a week and 7 to 8 lb. a month is sufficient. The treatment should be persevered with until the patient's weight is about the average for the height and age. The patient should be encouraged to take more exercise, but this should stop short of inducing undue shortness of breath. Physical drill and massage are of considerable assistance in increasing the energy needs of the body. Care should be taken not to eat more than usual after exercise, for this will neutralise any good effects of the exercise.

Thyroid extract has been used in the past rather indiscriminately, as it increases the basal metabolism. If the patient has a low metabolic rate (B.M.R.), it should be given; but if the B.M.R. is already normal, it may cause harm. The usual dose is 1 to 2 gr. twice daily. A careful watch should be kept for the onset of tachycardia, tremor, sweating, and glycosuria. When the B.M.R. is raised, more insulin has to be provided, and an elderly patient with a low sugar tolerance may develop glycosuria and have the symptoms of diabetes mellitus as the result of the administration of thyroid.

LIPODYSTROPHIA PROGRESSIVA

This is a rare condition, in which the subcutaneous tissues of the upper part of the body lose their fat, while those of the lower half remain unchanged.

Ætiology.—Females are affected more often than males. The cause of the condition is quite unknown.

Symptoms.—The patient feels perfectly well, but complains that the appearance of the face has altered, having become much thinner. The arms and trunk may also be similarly affected. The condition starts in the face and gradually descends to the arms and trunk. The legs are usually unaffected. On examination, the skin can be picked up easily and it is obvious that there is no fat in the subcutaneous tissue. The malar bones are very prominent. The whole appearance of the patient suggests a severe wasting disease. The breast and mons veneris in females are usually unaffected.

Course.—The condition progresses slowly.

Diagnosis.—This is made by comparing the subcutaneous tissues of the

upper half of the body with those of the lower. The presence of a severe wasting disease must of course be carefully excluded.

Treatment.—Nothing is known which has any effect on the condition. The patient should be assured that no serious disease is present.

THE LIPOMATOSES

Localised deposits of fat may occur in many situations. Various types with special symptoms have been described, but it is probable that they are only variations of a common morbid process.¹ The main types of the disease are:

1. *Adiposis dolorosa (Dercum's disease)*.—See p. 477.

2. *Nodular circumscribed lipomatosis*.—The lipomata may be few in number or very numerous, symmetrical or asymmetrical, large or small. Most of them are painless, but some are very tender and painful. Asthenia and mental changes, such as occur in *adiposis dolorosa*, may be present.

3. *Diffuse symmetrical lipomatosis of the neck*.—This condition occurs chiefly in males, and the tumour usually appears after the age of 20. The thyroid and pituitary glands showed pathological changes in two cases. The fatty tumour is diffuse and symmetrical. The common sites are beneath the chin, at the nape and base of the neck, and the pre- or post-auricular region, and occasionally on the trunk. The tumour bears no relation to the general obesity of the patient. It is usually complained of because of the disfigurement which is caused. Pain, asthenia and mental disturbances may be present.

4. *Neuropathic œdema, pseudo-œdema, pseudo-lipoma*.—Swelling of the limbs may occur in patients with hysterical affections. This resembles at first sight an œdematous swelling, but it does not pit on pressure. It is due to a deposition of fat in the subcutaneous tissues.

Treatment.—This is very unsatisfactory. Thyroid extract gr. i t.i.d.s., has given the best results, but pituitary extract should also be given a trial. Aspirin may relieve the pain.

GEORGE GRAHAM.

DEFICIENCY DISEASES

VITAMINS

The normal dietary of man and animals, consisting in its bulk of carbohydrate, fat, protein, mineral salts, and water, is not complete without containing certain substances called vitamins. The existence of vitamins as essential to a healthy dietary was first demonstrated by Sir F. G. Hopkins in 1912 under the term of *accessory food factors*. Osborne and Mendel, and McCollum and Davis, subdivided these unknown substances into two groups, called by McCollum *fat-soluble A* and *water-soluble B*, both groups together being necessary for life and growth.

¹ Lyon, *Arch. Int. Med.*, vi., 1910, p. 28

For a long time it had been known that certain diseases were connected with errors in diet. Thus, scurvy had been proved to be due to the absence of fresh fruits and vegetables. Rickets could be prevented and cured by the intake of fats, especially of cod liver oil. Beri-beri arose from the consumption of white rice, and was curable and preventable by the consumption of whole rice or the peelings of rice. Pellagra, which arose from a diet consisting mainly of maize, was curable by a change to food containing animal protein. Chemical investigations regarding the substance in rice polishings and other foods by Funk led to his isolation of an impure substance which was curative of beri-beri in pigeons, and which he called *vitamin*. This substance was very similar in its distribution in foods and in chemical properties to water-soluble B₂ and it appeared that the two substances were identical. The term vitamin became applied to water-soluble B; fat-soluble A became fat-soluble vitamin A; and, to bring the unknown substance in fruits and vegetables into line, this was called water-soluble vitamin C. Later, for the purpose of simplicity, these three vitamins were termed vitamin A, vitamin B, and vitamin C. The preventive substance of pellagra was considered to be an amino-acid, present in animal proteins, but absent from the proteins of maize and other cereals.

Each of the groups of vitamins has been found to be more complex. Three fat-soluble vitamins have been distinguished, and are known as A, D, E; whilst the water-soluble group comprises B or B₁, B₂ or PP (pellagra-preventing), and C. Rickets has been closely connected with vitamin D. Xerophthalmia and lowered resistance to infections follow from absence of vitamin A. Sterility of animals on purified diets follows if vitamin E is absent. Vitamin B or B₁ is associated with the prevention of beri-beri, and B₂ or PP with pellagra. Scurvy is connected with the absence of vitamin C.

The discovery of the existence of vitamins in different foods has resulted from feeding experiments on animals. They are present in the foods only in minute amounts, and on this account their isolation and characterisation is most difficult. In all cases very concentrated extracts can be made, and *vitamin D* has been identified as a substance produced from ergosterol by the action of ultra-violet light. A substance of the formula $C_6H_{10}ON_2$ has been isolated from rice polishings by Donath and Jansen, which substance is curative of beri-beri in pigeons and other birds. Vitamins are thus definite chemical substances with definite function in nutrition. A balanced diet consists not only in having the correct amount and proportion of carbohydrate, fat, protein, and mineral salts to give the necessary calories, but also it must contain a sufficient amount of each of the vitamins.

THE FAT-SOLUBLE VITAMINS

Vitamin A.—The presence of an unknown substance in fats became obvious from the fact that animals would grow on some fats, but not on others. The fats which made growth possible were mostly animal fats, with the exception of lard; the fat in green leaves was good, whilst vegetable fats extracted from seeds were not growth-promoting. The early work of Mellanby on experimental rickets showed a similar division of the fats into two groups. A comparison of the growth-promoting value of different fats

was made, and their values were found to be very different, as shown in the following table :

	Quantity per day for rats.
Cod-liver oil	0.02 to 0.002 gram.
Butter	0.2 to 0.4 gram.
Whole milk	2 c.c.
Cabbage	1.5 gram.

The high value of cod-liver oil in comparison with other fats was most striking. Other fish-liver oils have as high or even higher values. Some green leaves contain about three times as much vitamin A as butter does. Vitamin A is produced in the plant in the presence of chlorophyll, and it has been shown that butter contains more vitamin A in the summer than in the winter. The presence of vitamin A in milk and other animal fats has been demonstrated to come from the green foods which the animal consumes. Other investigations upon the stability of the vitamin showed that it was destroyed by heat in the presence of air. Heating in closed vessels, however, was not destructive. Chemical examination of fats has located vitamin A in that portion of the fat which is not converted into soap by means of soda, i.e. in the unsaponifiable matter. It has also been possible to detect vitamin A in fats by means of a colour reaction with arsenic or antimony chloride in chloroform. Fats containing vitamin A give a purple colour, which gradually fades (Rosenheim and Drummond).

Vitamin D.—Though the early work suggested that the fat-soluble vitamin promoting growth and preventing xerophthalmia in animals was the same as the antirachitic substance, there were several differences in the behaviour of the fats. McCollum found that cod-liver oil, after aeration at a high temperature, was still antirachitic, but did not prevent xerophthalmia. The antirachitic substance was thus stable to heat, and different from the growth-promoting vitamin A. The existence of two vitamins in fats was also shown from experiments with spinach. Spinach was strongly growth-promoting and anti-xerophthalmic, but it failed to prevent rickets. McCollum called the antirachitic substance vitamin D. A special rickets-producing diet had been evolved for the purpose of these experiments. It had a ratio of calcium to phosphorus of 5 to 1 ; which is much higher than the ratio of 2 to 1, that of calcium phosphate. The demonstration of rickets was carried out either by analysis of the bones, or by X-ray tests, or by a "line" test of the growing bone. Calcification in this test is shown by a reaction of freshly deposited calcium phosphate in the bone with silver nitrate at the epiphyses. A negative or faint line test indicates lack of, or poor, calcification. The differentiation of two vitamins from these experiments gave the explanation of the irregular antirachitic action of fats. Some contained both vitamins in large amounts, e.g. cod-liver oil ; others, like butter, much vitamin A and little vitamin D ; and others, like spinach, had much vitamin A and no vitamin D.

The curative action of sunlight upon rickets was well known, and could not be explained by the existence of vitamins. Hulschinsky, in 1920, demonstrated the curative action of ultra-violet rays from a mercury vapour lamp, and it then became possible to study the action of light experimentally. It was observed by Hume and Smith, at the Lister Institute, that rats kept

in cages exposed to ultra-violet light did not get rickets, and that these rats owed their health to the fact that they ate the sawdust which had been used as bedding of the cage. Rats in control cages, with sawdust not exposed to ultra-violet light, suffered from rickets. The light had thus produced something in the sawdust which gave the effect of vitamin D in preventing rickets. Foods of various kinds which usually led to rickets were next exposed to ultra-violet light and made antirachitic, and the substance which became activated was located in the fat. The constituents of fats were separated, and the constituent was found to be present in the unsaponifiable matter. Cholesterol isolated from fats was found to be capable of activation by ultra-violet light, and other specimens of this compound were also found to be rickets-preventing if exposed to ultra-violet light. Further examination of cholesterol led to the discovery of an impurity in the cholesterol, which was the substance capable of activation. The impurity was shown by Rosenheim, Heilbron, and others to be the closely allied ergosterol. Rosenheim has examined other members of this group of compounds, and has proved that only ergosterol can be activated and become vitamin D. Sunlight, owing to its ultra-violet rays, prevents rickets by converting ergosterol in the fat under the skin into vitamin D. Two factors are thus needed in the prevention of rickets. The one is ergosterol, the other ultra-violet light. Foods may contain ergosterol or activated ergosterol. The latter will prevent rickets; and the former will prevent rickets after exposure to ultra-violet light, either directly or after consumption by an animal through its skin. The direct irradiation of foods is not altogether practicable. The food may become unpalatable, and over-irradiation may destroy the vitamin D which is formed, and at the same time any vitamin A present in the food is destroyed by ultra-violet light. Though ergosterol is a rare substance, it can be isolated from ergot and from yeast, and subsequently irradiated. It is possible to obtain such preparations, and certain ill-effects have been described from overdosage of vitamin D. These ill-effects may be due to the formation of other substances by the action of the light rather than to the action of excess of vitamin D. The correct and natural method of securing vitamin D by taking ergosterol in the food and causing its activation by sunlight is in most cases preferable to the use of vitamin D preparations. There is at present no information of the amounts of vitamin D in the foods. Minute quantities are needed. In the case of baby rats 1/10,000 milligram a day will prevent rickets. This quantity corresponds to an amount of about 2 milligrams per diem for a child. Besides being antirachitic, vitamin D appears to be the fat-soluble vitamin the absence of which from the diet leads to phosphatic calculi in the kidney (Van Leersum).

Vitamin E.—It has been repeatedly shown that rats could be reared on a diet of pure protein, fat, carbohydrates, and mineral salts, together with cod-liver oil to supply vitamins A and D, and yeast to supply vitamin B. Vitamin C is not needed by the rat. On such diets, however, the animals failed to reproduce. The presence of another essential substance to enable the rats to reproduce was announced by Evans and Bishop in 1922, and the work has been corroborated many times. The addition of lettuce or other green leaves, of whole cereals, especially of the germ of cereals, to the food, resulted in normal reproduction. The substance is another vitamin,

and is termed vitamin E. Like the other fat-soluble vitamins, vitamin E is present in the unsaponifiable portion of the oil of wheat germ, and is a comparatively stable substance. It is present in many foods, and consequently on an ordinary mixed diet there does not appear to be any likelihood of its absence from the food.

THE WATER-SOLUBLE VITAMINS

Vitamin B or B₁.—The work of Eijkmann, who observed that fowls suffered from a peculiar form of paralysis called *polyn neuritis gallinarum* on being given a diet of white rice, and its cure with whole rice or the peelings of rice, led to the testing of other foods for the presence of the anti-beri-beri substance. Subsequent work on the values of different foods as a preventive of beri-beri was carried out by Cooper, and by Chick and Hume at the Lister Institute, using the pigeon as test animal. Their data were very similar to those resulting from the examination of different foods for water-soluble B, as tested by the growth of rats. The identity of these two seemed certain. There were, however, some differences, and it appears that the unknown in these foods is two unknowns. They have been provisionally termed B₁ and B₂ by the Vitamin Committee of the Medical Research Council: B₁ the vitamin preventing beri-beri, and B₂ the vitamin promoting growth and concerned in the prevention of pellagra. The differentiation of the two vitamins is also proved by the difference in their stability to heat. B₁ is destroyed by high temperatures, especially in presence of alkali; B₂ is stable to these conditions. Vitamin B₁ and vitamin B₂ are present in different amounts in a few foods, though in most foods the amount is nearly equal. Yeast contains both; wheat germ has more B₁ than B₂; and egg white has B₂, but not B₁.

For purposes of nutrition it is important to know the comparative values of the different foods in respect to vitamins. A long series of experiments on the vitamin B or B₁ values has been made by Plimmer, Rosedale, Raymond, and Lowndes, using the pigeon as test animal. Their values are given in the following table:

	Percentage amount required in a Diet of White Flour.
Dried yeast	4
Wheat germ (Bemax)	6
Yeast extract (Marmite)	10
Peanuts, hazel nuts	20
Dried peas, lentils, etc.	30
Whole wheat, rye, barley, etc.	40
Egg yolk	50
Potatoes, artichokes	80
Oranges, parsnips, kale	70

These figures are the minimum amounts needed to prevent polyn neuritis. The tests with other fruits and vegetables have not shown the presence of any appreciable amount of vitamin B. Vitamin B is most abundant in the germ of seeds, and is not usually found in other parts of plants. Egg yolk,

liver, and other internal organs of animals contain vitamin B. Experiments with rats have shown that this animal requires only about half the amount of vitamin B as the pigeon. Man's requirements are usually regarded as similar to those of the rat. The figures show that, in order to supply enough vitamin B for health, a normal diet should contain a very large proportion of whole cereals. As an alternative, in the case of a common diet of white flour and sugar, the addition of yeast extract or wheat germ is necessary, in order to introduce vitamin B, the quantity being about $\frac{1}{8}$ th of the total dry weight of the food, i.e. from $\frac{1}{2}$ to 1 oz. per diem. Experiments on birds regarding vitamin B values of foods have shown that the food should be balanced by vitamin B, and that if this is not so the animals live for shorter or longer periods, depending on the quantity of vitamin B, and then die without showing the typical symptoms of paralysis, but with enlargement of the heart and various other internal morbid affections. These morbid affections have been described by McCarrison as the preliminary stages of beri-beri, caused by an absence of vitamin B. In the case of too small amounts, i.e. a shortage, of vitamin B, the internal morbid affections noted become chronic. Further investigations by M. J. Rowlands on rats on too small amounts of vitamin B have shown distension of the stomach, loss of mucosa and muscular coat of the intestinal wall, and delayed excretion, signifying indigestion and constipation. The loss of mucosa and muscular coat further allowed bacteria to penetrate through the lymph channels into the general system. The importance of sufficient vitamin B in the diet is thus clearly established. A scrutiny of an ordinary diet for its amount of vitamin B will usually show a deficiency of this vitamin, which deficiency is a probable cause of many cardiac and digestive symptoms.

Vitamin B₂ or PP.—Pellagra was originally thought to be due to the absence of animal proteins from the food. The chemistry of proteins has shown that animal proteins contain a greater variety of amino-acids than vegetable proteins, and hence the unknown substance preventing pellagra was considered to be some amino-acid. Experiments did not, however, specify any particular amino-acid. The more recent work of Goldberger has indicated that pellagra is not caused by a lack of animal protein, but rather by the absence of some definite vitamin. This vitamin is most abundant in yeast, and is present in lesser amounts in wheat germ, meat, fish, eggs, and internal organs of animals. Its distribution is thus very similar to that of vitamin B₁. The water-soluble vitamin is thus often a complex, and, as mentioned previously, the part concerned in the prevention of pellagra is heat-stable, and is termed vitamin B₂. As vitamin B₂ is present in meat, eggs, fish, and other articles of food, the appearance of pellagra in countries using these foods is rare, and can then generally be traced to peculiarities in the diet. A study of the pellagra producing diets by Wilson showed that they contained too little animal protein, and that 40 grams of animal protein per diem prevented the disease.

Vitamin C.—In the Middle Ages it was recognised that fresh fruits and vegetables cured and prevented scurvy, that dried fruits and vegetables had no effect, and that among fruits the orange and lemon were the best antiscorbutics. A ration of 1 oz. of lemon juice per diem was served out in the navy, and was found to prevent scurvy. A smaller ration of $\frac{2}{3}$ oz. was found to be insufficient. The modern experimental work of Holst and

Frölich, who discovered that the guinea-pig on a diet without fresh fruits and vegetables suffered from scurvy, led to an examination of the comparative vitamin C values of this class of foods by Chick and Hume, whose experiments were carried out during the Great War, largely to ascertain the best antiscorbutics for army use. These investigations were extended in other directions, such as the effect of cooking, and the addition of soda and citrate to milk. The following table shows the chief results:

Minimum Daily Quantity to Protect from Scurvy.		
	Guinea-pig	Man.
Orange or lemon juice	1.5 grams	1 oz.
Tomato juice	2.0 "	1.5 "
Lime juice, <i>fresh</i>	5.0 "	3.5 "
Apple	10.0 "	6.6 "
Banana	10.0 "	6.6 "
Grapes	20.0 "	13.3 "
Cabbage	1.5 "	1.0 "
Green peas ✓	2.0 "	1.3 "

The figures for man in this table are calculated from those found for the guinea-pig, taking 1 oz. of lemon juice as the basis. Fruits and vegetables vary very much in their antiscorbutic value: some have a high value; whilst others, like grapes, beetroot, and turnip, have a low value. Milk also has a low antiscorbutic value. These values are now being made use of in practice. Orange juice, instead of grape juice, is commonly given to infants to avoid infantile scurvy.

The effect of cooking fruits and vegetables is destructive of vitamin C. Rapid cooking is less harmful than long slow cooking. The heating of vegetables a second time destroys vitamin C, so that reheating of cooked cold vegetables is inadvisable. The practice of cooking with soda has been found to be destructive, and similarly with bicarbonate, or the use of citrate with milk. Vitamin C is very sensitive to heat in the presence of air. On account of the easy destruction by heat, the tinning of fruits was considered fatal to vitamin C, but direct experiments with tinned fruits has shown that the vitamin C is not destroyed. In the modern process of canning, air is removed from the fruit before heating, and there is little or no destruction. Jams and marmalade are produced by long boiling, and therefore do not contain vitamin C. The preparation of condensed and dried milk by processes in which air is excluded gives a material containing vitamin C. Orange juice has also been concentrated, and contains the original vitamin C value. It is of importance to notice that dried peas and beans develop vitamin C on

being sprouted. They can thus be used as a source of vitamin C on long expeditions far from a base, and if fresh vegetables are scarce.

R. H. A. PLIMMER.

SCURVY (SCORBUTUS)

Scurvy belongs to the group of "deficiency" diseases, being due to the absence from the diet of a sufficiency of a specific "accessory food factor" or "vitamin." It consists in a general disorder of nutrition, characterised by debility, mental apathy, *anæmia*, sponginess of the gums, ulceration of the mouth, and a tendency to hæmorrhage.

Ætiology.—The theories, long entertained, that scurvy is the result of poisoning by a ptomaine or of a deficiency of potassium salts or alkaline compounds in the blood, have now been abandoned, and it has been abundantly proved by the experimental work of Axel Holst and his successors that the disease results from a deficient intake of an anti-scorbutic vitamin. The chemical nature of this vitamin is unknown, nor do we understand how its absence produces the change in nutrition which results in scurvy; but it is known to be present abundantly in green vegetables and the juice of fresh fruits, especially of oranges and lemons; in considerable amount in roots and tubers, and in small quantities in raw meat juice and milk. It is absent from dried vegetables and seeds, though it appears in the latter as the result of germination. It is very sensitive to heat and to drying, and is destroyed by alkalis, but protected by acids. Bad hygienic conditions appear to favour a development of the disease; but as a rule it seems to require an exposure of from 4 to 8 months to scorbutic conditions before it appears.

Pathology.—The only constant change found after death is effusion of blood into the skin and subcutaneous tissues and under the periosteum, and sometimes also in the pleura and pericardium. The effusions are diffuse or circumscribed, and may show partial clotting or even organisation. There may also be hæmorrhagic effusion into joints. The organs show no constant change, but the heart muscle may be soft and degenerated, the lungs œdematous, and the spleen congested and infarcted.

Symptoms.—Scurvy is a disease of insidious onset. The earliest symptoms are weakness and lassitude, dizziness on standing up, and bruising or bleeding from the gums on slight provocation. Pains in the lower limbs are often complained of, and there may be a characteristic hardness of the calf muscles. Follicular keratosis is an early sign (Wiltshire), and in appearance is similar to the hyperkeratosis of follicles met with in other malnutritional states. Meanwhile the patient looks ill. The face becomes sallow and drawn, and the eyes lustreless and encircled by dark rings.

Such symptoms may precede by a few days, or even weeks, the more characteristic signs. Among these the most striking, though not necessarily always present, are the changes in the mouth. The gums begin to swell, especially around stumps or carious teeth, and as the process goes on the swelling may become so great as to amount to a veritable hypertrophy, so that the teeth become buried in a mass of soft fungous tissue of a bluish or purplish tint. Ulceration quickly follows along the margins, the process

being accompanied by the discharge of a sanious fluid which imparts an odour of great fœtor to the breath. Finally, the teeth become loosened in their sockets and may fall out, while necrosis of the alveolar edges ensues.

Equally characteristic and constant are hæmorrhages into the skin and subcutaneous tissue, which assume the form either of petechiæ or of ecchymoses. The former occur as small red or purple spots resembling flea bites, which appear first around the hair follicles of the lower extremities, and impart, by the elevations which they produce, a slight feeling of roughness to the skin. They remain for about a week, and then gradually fade into greenish spots, which soon disappear; their disappearance being followed by a slight degree of desquamation. The production of the petechiæ is determined by the slight irritation caused by the friction of the clothes, and hence they are always to be found first on the outer surface of the leg, and the outer and anterior aspects of the thigh. Here and there the petechiæ may coalesce into larger areas or maculæ. In severe cases the slightest pressure on the skin is sufficient to cause ulceration, the ulcers having thick edges and bleeding surfaces with offensive discharge. Such ulcers may spread rapidly and invade surrounding tissues, giving rise in some cases to dangerous, and even fatal hæmorrhage. Ecchymoses, the other characteristic surface lesion of scurvy, are produced by hæmorrhage into the subcutaneous or intermuscular tissue. They may occur spontaneously or as the result of injury, and vary greatly both in size and extent, being commonest in the lower extremities, where they may form quite large swellings. The part affected by them is brawny, tender, and pits on pressure, the indentation persisting longer than it does in ordinary œdema. The skin over them is red, shiny and hot. Such effusions are common, also, in the popliteal space and in the bend of the elbow, as well as in the loose tissue around the malleoli, and beneath the muscles of the jaw. In these situations they form indurated swellings which fill up the natural hollows of the part, and greatly interfere with the movements of the adjacent joint. Where such effusions occur over the shins they are apt to be mistaken for syphilitic nodes. There is no marked tendency to bleeding from the internal organs; but hæmorrhages may take place from the mucous surfaces. Of such hæmorrhages, epistaxis and bleeding from the mucous membrane of the mouth are commonest. Bleeding may also occur from the mucous membrane of the intestine when there is a coexisting diarrhœa. Hæmoptysis, hæmatemesis and hæmaturia are rare. Hæmorrhagic effusion into the pleura and pericardium has also been described. Not uncommonly hæmorrhage occurs under the conjunctiva, and may be so extensive as appreciably to raise the ocular layer, leaving the cornea at the bottom of a pit surrounded by swollen and red conjunctival membrane.

As the disease progresses anæmia becomes a marked feature, though its degree has no constant relation to the extent of the ecchymoses. The blood picture is that of a secondary anæmia, the red cells being sometimes reduced to 2 millions per c.mm., or less. Poikilocytosis and anisocytosis are common, nucleated forms rare. The hæmoglobin is reduced roughly in proportion to the red cells. Observers differ as to the white cell count. Some have described a leucopenia; others a moderate lymphocytosis. All are agreed that polynuclear leucocytosis is not present unless inflammatory complications coexist. Apparently the coagulability of the blood is not diminished,

and the serum is not hæmolytic; but although the presence of a diminished alkalinity has been alleged our knowledge of the chemical changes in the blood is still limited.

Alimentary symptoms may be absent. Appetite is not necessarily impaired; but dyspepsia may be present, as the result of the dietetic conditions which produce the disease. Constipation is the rule; but the conditions in which scurvy develops often favour the production of a dyspeptic type of diarrhœa with sanguineous discharge. The urine may be albuminous.

Complications.—Gangrene of the lung is one of the most frequent and dangerous of the complications. Bronchitis and bronchiolitis also occur. Night blindness is met with not unfrequently, and is specially prone to occur in patients who have been exposed to bright light, and may be an early symptom. It is associated with anæmia of the retina.

Diagnosis.—If all the characteristic symptoms are present, and if the disease arises simultaneously in a number of subjects in circumstances known to favour its development, the diagnosis is easy. Difficulty only occurs when one has to deal with sporadic cases, such as those of land-scurvy, met with in ill-fed individuals.

The disease which perhaps most closely resembles it is purpura hæmorrhagica (morbus maculosus of Werlhof): but in this the affection of the gums is absent, and the hæmorrhages have not, as they have in scurvy, an inflammatory character. Mercurial cachexia, which in many points closely simulates scurvy, is now but rarely seen, and an inquiry into the history will usually lead to a correct conclusion. Acute lymphatic leukæmia, which is so often marked by ulceration in the mouth, can be distinguished by an examination of the blood.

Prognosis.—This, except in the severest cases, is favourable, provided that proper treatment is adopted. The outlook depends less upon the severity of the local lesions than upon the condition of the internal organs, and the presence or absence of complications. Extensive bronchitis or severe diarrhœa is of grave omen, and gangrene of the lung nearly always proves fatal. Even in uncomplicated cases, sudden death may be brought about by severe hæmorrhage or heart failure. In the most favourable circumstances convalescence is apt to be protracted, and when recovery is otherwise complete there may still be results left behind in the shape of cicatrices in the skin or partly ankylosed joints.

Treatment.—The essence both of the prophylaxis and of the active treatment of scurvy is to supply a sufficiency of the anti-scorbutic vitamin in the diet. With this object, salads of fresh uncooked vegetables, if obtainable, should be partaken of freely, and other vegetables should be cooked for as short a time as possible—no soda being added in the process. The juice of fresh lemons or oranges may be taken to the amount of an ounce daily. Ordinary bottled lime juice is useless. Fresh meat and milk, fresh or soured, are also helpful. If none of the above can be had use may be made of germinated peas, beans, or lentils—especially in prevention. Tinned fruits and tomatoes have also some anti-scorbutic power.

In addition to the dietetic measures, if the disease has actually developed, the patient should be removed as soon as possible to more hygienic surroundings. Cold and damp should specially be avoided. Drugs are of

little help, but iron may be given during convalescence. Cod-liver oil has been recommended for the night blindness. Other complications must be treated according to their nature. Locally the condition of the mouth will demand most attention. A peroxide wash will help to remove the fœtor, whilst nitrate of silver solution (2 to 3 per cent.) may be painted on the affected gums.

INFANTILE SCURVY

Infantile scurvy—known on the Continent as Barlow's disease—is identical in its pathology with the adult form of the disease, its special clinical features being due to the anatomical and physiological peculiarities of early life.

Ætiology.—The disease usually appears between the eighth and twelfth months—both sexes being equally affected. As in adult scurvy, the essential cause is the absence from the dietary of a sufficiency of anti-scorbutic vitamin. A diet of condensed milk, with the addition of a tinned food, is that which most commonly results in scurvy; but sterilised milk alone may give rise to it, and so even may milk which has only been boiled. Desiccated or pasteurised milk does not appear harmful. A few cases have been recorded in which the child had been fed on the breast only; it is probable that in these the mother's diet had been deficient in fresh constituents.

Pathology.—The chief changes are in the neighbourhood of the bones. A section made across a limb at the site of a swelling shows that the periosteum is hyper-vascular, thickened and separated from the subjacent bone by a layer of partially organised blood clot. There is no sign of inflammation, and no hard bone is formed in the periosteum, except in very long-standing cases; in which circumstances the muscles surrounding the bone may be infiltrated with blood or serum, and look sodden. The bone exhibits rarefaction, and may be fractured. There may be hæmorrhagic effusions into the joints or serous cavities. The organs exhibit no characteristic change.

Symptoms.—The onset is gradual, the first symptoms noticed being often a refusal of food, along with fretfulness and restlessness. There is a tendency for the child to resent being handled. Meanwhile the general nutrition is usually unimpaired, and the child's colour is often fresh and healthy looking. After a variable period the more prominent symptoms appear. The most striking of these is extreme tenderness of the legs, which causes the child to scream loudly when touched or even when approached. In a well-marked case some swelling will be found, usually of the lower end of the femur or upper end of the tibia. Involvement of the arm bones is much rarer. The skin over the swelling is often tense and glossy, and may be slightly œdematous; but there is no local heat. Soft crepitus may be elicited on handling the limb, indicating a fracture or a separation of the epiphysis. In some cases hæmorrhage takes place into the orbit, giving rise to proptosis and ecchymosis of the eyelid. Rarer sites of hæmorrhage are around the ribs, clavicles or bones of the skull.

Changes in the gums are not nearly so pronounced as in adult scurvy, and are not usually present, unless some teeth have been cut; in that case the gum around them is usually swollen and of a purplish colour. Petechiæ

and subcutaneous ecchymoses are very rare in infantile scurvy, and hæmorrhage from mucous membranes is not common. Hæmaturia, however, is not infrequent, and may be an early and the only symptom; it is probably often overlooked. Fever is not a conspicuous feature, but may be present if extensive hæmorrhages have taken place; it rarely exceeds 102° F. The blood changes are the same as have been described in the adult form of the disease.

Diagnosis.—This is easy in a well-marked case, provided the leading features of the disease are known to the observer. The screaming of the child on examination, the swelling and tenderness of the legs, and the condition of the gums leave no doubt as to the nature of the affection with which one has to deal. All cases, however, are not so pronounced in type. Not infrequently one encounters mild or incipient forms which it is easy to overlook. In these, tenderness when the child is handled, or when it is put in the bath, may be the only symptom. In other cases again, slight sponginess around the incisor teeth may alone be present, or one may have to deal with an apparently causeless hæmaturia. In any case in which there is doubt two points will help. One is the nature of the feeding. If this has been of such a kind as is known to favour the development of the disease the diagnosis will be greatly strengthened. The other point is the application of the therapeutic test. If the symptoms present are really due to incipient scurvy then they will certainly disappear rapidly so soon as appropriate treatment is begun; if they fail to do this, then some other condition must be thought of.

Infantile scurvy may be mistaken for rheumatism, although the mistake should not occur if it be remembered that acute rheumatism is hardly ever seen below the age of 2. The distinction between scurvy and suppurative periostitis or epiphysitis is much more difficult, especially if the gum changes are absent. A very high temperature and much constitutional disturbance are against scurvy. The nature of the diet will also be of weight in the diagnosis. A skiagram will be of great assistance in coming to a conclusion.

The absence of swelling in the affected limb and of the other symptoms of scurvy should distinguish those cases of infantile paralysis in which there is much tenderness of the paralysed leg, and the blood examination should enable one to differentiate a case of acute leukæmia or chloroma.

Prognosis.—This is quite favourable, provided the disease is recognised in time and proper treatment adopted. Nothing in therapeutics is more striking than the rapidity with which such patients improve on a change of diet, although some degree of thickening of the bones may persist for a long time. Death, when it occurs in the more severe cases, is usually the result of intercurrent disease, such as broncho-pneumonia and chronic diarrhœa, although sudden hæmorrhage, cardiac failure or exhaustion may occasionally lead to a fatal issue.

Treatment.—This consists mainly in altering the diet. Tinned foods and sterilised milk must be stopped at once, and the child put upon a due allowance of unboiled milk. Four teaspoonfuls of orange or grape juice, sweetened with a little sugar, should be given daily. Baked potato is also useful, a little of the part under the skin being rubbed up with the milk into a thin cream, which is either added to the bottle or given separately (2 teaspoonfuls three or four times a day). Raw meat juice is of some value,

especially if anæmia is present, and may be given in quantities of half an ounce daily. Drugs are of little service; but cod-liver oil and iron aid convalescence.

Scorbutic infants should be handled carefully, and the clothing so made that it can be easily taken off and on. If it is necessary to move the child about it should be carried on a pillow. The affected limb should be steadied by light splints or wrapped in wet towels, which, if allowed to dry in position, afford considerable support. In mild cases a covering of cotton-wool secured by a light bandage is sufficient protection.

RICKETS

Definition.—Rickets is a disease of nutrition occurring in early childhood. It mainly affects the growth of the bones, but is characterised also by a tendency to catarrhs of mucous membranes, and to functional disorders of the nervous system.

Ætiology.—Various theories have been held in the past as to the cause of rickets. It has at different times been attributed to inherited syphilis (Parrot), to microbic infection, to dyspepsia the result of dilatation of the stomach, and to obscure nervous influences. More plausible was the belief that it resulted from a deficient intake of lime. All these views, however, are now discredited, and it is generally agreed that the disease results from some error in feeding. Clinical observation has long pointed to a deficiency of fat as being the essential fault in the diet: but recent experimental work favours the view that it is not a deficiency of fat as such that is responsible, but of a fat-soluble vitamin (vitamin D). This vitamin is present in milk fat, but is particularly abundant in cod-liver oil. It can be produced artificially by the irradiation of ergosterol.

In addition to the food factor there is no doubt that defective hygiene—including in that term overcrowding, insufficient air, exercise, and light, and, in fact, the conditions of life of the poorer class in large towns generally—plays a very large part in predisposing to the disease. Noel Paton and the Glasgow School even consider that the domestic factor alone is sufficient to cause the disease, apart from errors of diet. All are agreed that the disease is mainly one of temperate climates, that it is more apt to develop in the winter and affects both sexes equally, and that heredity plays no part in its production.

Pathology.—The chief changes are in the bones. Section through the end of a long bone shows that ossification, instead of proceeding in an orderly way, is greatly disorganised. In the zone of proliferation of the cartilage the cells show excessive multiplication, and are arranged irregularly, instead of in columns. A broad bluish area results, which is the cause of the thickening of the epiphysis. In addition to this, calcification between the cells is defective, the affected area shows excessive vascularity, and the new bone formed is soft and deficient in lime. The whole process has been summed up in the statement that “there is an excessive preparation for ossification and a defective accomplishment of it.” In addition, the vascular layer of the periosteum is thickened and the marrow congested.

Chemical analysis shows that the bones contain only from 30 per cent. to

50 per cent. of calcium, instead of the normal 60 per cent. or more. They may show signs of old or recent fracture. The poverty of the bones in mineral matter appears to be due to defective absorption and utilisation of calcium and phosphorus, which is the chief feature of the morbid chemistry of the disease. The internal organs show much less change; but the spleen may be rather large and firm, from an increase of its fibrous tissue, and the liver is often somewhat fatty. The mucous membranes of the respiratory and alimentary tracts frequently exhibit evidences of catarrh.

Symptoms.—The disease can rarely be recognised before the sixth month. Amongst the earliest indications to attract attention are restlessness and irritability, sweating about the head, especially when asleep, and a tendency on the part of the child to kick off the bedclothes at night. There is no wasting, indeed the infant may be abnormally fat, though usually flabby and pale. The appetite is capricious.

As the disease progresses, it will be found that dentition is delayed, and that changes in the bones become manifest. They first show themselves in the epiphyses of the ribs, which enlarge and form a row of knobs down the sides of the chest (the rickety rosary). Enlargement of the epiphyses of the bones of the limbs then takes place, being most conspicuous at the lower end of the radius.

The softening of the bones leads to various deformities. The chest sinks in at the line of junction of the ribs and cartilages, so that a broad groove forms, running downwards and outwards towards the axilla (Harrison's sulcus). The bones of the limbs bend, the femur curving forwards and outwards, and the tibia bending sharply forwards and often also outwards at its lower third; there may also be a curving of the upper part, leading to "bow-leg." The humerus and bones of the forearm may become bent in an outward direction, as the child sits supporting itself on the hands, and the clavicle may show a sharp kink at the junction of the inner and middle third. The pelvis becomes flattened. Greenstick fractures of the limb bones are not uncommon.

The skull shows striking changes. It is usually somewhat enlarged, elongated and flattened on the vertex (box head), the anterior fontanelle remaining widely open long after the normal period of closure at the eighteenth month. There may be pronounced thickening of the frontal and parietal eminences, leading to the so-called "hot cross bun" or bossed head, especially in cases complicated with *anæmia* with enlarged spleen. Areas of defective ossification in the parietal and occipital bones in the neighbourhood of the occipital suture (cranio-tabes), which yield on pressure a characteristic parchment-like sensation, are not uncommon.

The muscles are often so weak and flabby that paralysis is simulated, and the ligaments may be so lax that the limbs can be bent into almost any position ("acrobatic rickets"). In consequence also of the laxity of ligaments, kyphosis often develops in the lower lumbar region (rickety spine).

The blood usually shows a varying degree of *anæmia* of the secondary type, and in a few cases the changes are so profound as to resemble those met with in chlorosis.

The digestive system is usually deranged. Chronic diarrhoea with pale, offensive stools is not uncommon. The abdomen is distended so that the child has a pot-bellied appearance. In the production of the distension,

muscular weakness, intestinal fermentation, and the pushing down of the diaphragm by the sinking in of the chest all play a part. The edge of the liver can often be felt at a lower level than normal, partly from displacement and in part from enlargement through fatty change. The spleen is also palpable in a considerable number of cases, although this is due more to its being pushed down than to actual enlargement.

In the respiratory system bronchial catarrh is very often present, and not uncommonly results in broncho-pneumonia. In the nervous system the disease shows itself by general nervousness and irritability, and in some cases by the development of laryngismus stridulus, tetany, or even convulsions, of all of which rickets is a strong predisposing cause.

Diagnosis.—In a fully developed case the diagnosis is easy. Early cases, and those in which the rickety element is overshadowed by some complication, such as broncho-pneumonia or diarrhoea, are more apt to be overlooked. The suggestive points will be delayed dentition, an open fontanelle, and the presence of the rickety rosary. A skiagram will show a tendency to cupping of the diaphysis; the epiphyseal line will be irregular and ill-defined, and the epiphysis itself poorly ossified. There will also be a tendency to osteoporosis throughout the whole bone. The appearance of the epiphyses of the carpus and tarsus may be retarded.

The rickety head is apt to simulate hydrocephalus, but in the latter condition the skull is more globular, and bulges above the ears, the fontanelle is tense, and the eyeballs, in marked cases at least, pushed downwards. The kyphosis of rickets may be mistaken for spinal caries; but in the former the bend straightens out as a rule when the child is held up by the armpits. In severe cases this may not happen, and a radiograph may be required to settle the diagnosis. If the muscular weakness is pronounced infantile paralysis may be imitated; but the history, the retention of the reflexes, and the presence of other signs of rickets should prevent mistakes.

Prognosis.—Rickets is not fatal *per se*, and usually passes off spontaneously after the third year, although the deformities of the bone may persist for a long time. Even these, however, have a wonderful way of righting themselves without any special treatment. On the other hand, rickets is a very serious complication of other diseases, especially of broncho-pneumonia and diarrhoea, and adds greatly to their fatality if present, so that the dictum of Sir William Jenner that "in its indirect results rickets is one of the most fatal diseases that peculiarly affect childhood" is perhaps true.

Treatment.—Rickets can be prevented if the child is properly fed and cared for. Breast feeding for the first 9 months is the best safeguard; but it must always be remembered that the disease is apt to develop in children who are kept too long on the breast. After weaning, pure cow's milk should be given in sufficient quantity, and the premature or excessive use of starchy foods avoided. Care should be taken that the diet contains an adequate amount of animal fat. Plenty of fresh air, sunlight and exercise are also important factors in prophylaxis.

If the disease has already developed, the diet should be altered in accordance with the requirements indicated above, the most important point usually being to increase the allowance of cow's milk, which should not fall below $1\frac{1}{2}$ pints per diem during the second year of life. Yolk of egg is also a valuable food. Cod-liver oil (or one of the artificial substitutes containing vitamin D)

is the most useful drug, having almost a specific influence on the disease ; but iron may also be given with advantage if there is anæmia. Sun-baths or exposure to the rays of the mercury-vapour lamp have a definitely curative effect.

To prevent bending of the legs, long splints may be applied, projecting beyond the feet, so as to make standing impossible. Orthopædic treatment may be required for the more permanent deformities. Alimentary and respiratory complications should be treated by the measures appropriate to them.

LATE OR ADOLESCENT RICKETS

This term is applied to a disease apparently identical with ordinary rickets in its bony changes, but which sets in much later, usually between the ninth and fourteenth years. The patient may have been the subject of ordinary rickets in earlier childhood—hence the use of the term “recrudescent rickets”—or the disease may have appeared at the later age for the first time. Nothing is known of its causation.

The manifestations of the disease are practically confined to the skeleton, the long bones being particularly affected. The epiphyses become much enlarged, and pronounced deformities ensue as the result of bending. The skull escapes almost entirely, and there is no tendency to any disease of the internal organs, or to complications.

The disease is not dangerous to life ; but the deformities may be lasting. The general treatment is the same as that of ordinary rickets : but most cases will require the help of the orthopædic surgeon.

“Fœtal” and “congenital” rickets are ambiguous terms which have been loosely used to cover several distinct pathological conditions, amongst which are achondroplasia, mollities ossium, and osteogenesis imperfecta. They are best avoided. So-called “scurvy-rickets” and “acute rickets” are identical with infantile scurvy, although rickets often coexists with the latter, seeing that both are due to faulty feeding.

ROBERT HUTCHISON.

BERIBERI

Synonyms.—Polyneuritis Endemica ; Kakké ; Barbiers, etc.

Definition.—A vitamin-deficiency disease, occurring frequently in tropical regions, especially where rice is used as the sole article of food, characterised by peripheral neuritis, the nerves of the legs and heart being specially prone to attack.

Ætiology.—The disease is very frequent in the Federated Malay States, Sumatra, Japan, in parts of Brazil and in other parts of the world. Many cases reach London, cases from the Chinese, Japanese and Indian crews of steamers trading with India and the East. A well-marked form is found in sailing ships in the Atlantic (Ship Beriberi). Adults are most affected, but children also may suffer. Males and females appear to be equally susceptible.

It has now been abundantly proved that the cause of the disease is a vitamin deficiency. Though the disease is specially rife in rice-feeding races, rice *per se* is not essential, any food if deficient in the anti-neuritic

principle, the water-soluble B, being sufficient. This explains the attacks in Brazil, where rice is not used, and in the sailing ships, where stale and tinned foods are principally eaten—the high sterilisation required in tinning food destroying the vitamin. As regards rice, the vitamin is found in the pericarpal layer of the grain, and its removal by polishing renders it dangerous as food.

Pathology.—It is not yet clear how the absence of the vitamin or anti-neuritic principle acts; the changes found in the nerves being very similar to those found in alcoholic and other poisons.

A diet consisting of polished rice alone is completely deficient in vitamin, and this accounts for natives who use such a diet being specially liable to be attacked by beriberi. (Compare the experimental work on avian beriberi in pigeons.) A mixed diet, on the other hand, though deficient in part in the anti-neuritic principle or water-soluble B, may have in the other part quite enough to prevent the occurrence of any metabolic disturbance of the nerves.

Characteristic changes are found in people who have died of beriberi. The veins of the neck are engorged, the right heart is much dilated and distended with blood, and serous effusions are seen in the pleural cavities, pericardium and the cellular tissues. The lungs are congested and oedematous, the liver and spleen show chronic venous congestion. The duodenum is congested and reddened (the duodenitis of Hamilton Wright). The kidneys do not show nephritis. The nerves microscopically are much degenerated, the changes being similar to those seen in multiple peripheral neuritis due to other causes, namely, fatty degeneration of the myelin sheath, with gradual absorption, and finally disappearance of the axis cylinder and collapse of the sheath of Schwann, the nerve disappearing in the fibrous connective tissue of the endoneurium.

Symptoms.—The disease is variously divided up clinically, such as wet, dry and mixed forms. Hamilton Wright described rudimentary cases, ordinary typical cases and acute pernicious forms, and such a division is better than the former, the conditions really being similar in all, though of varying grades of severity. A wet beriberi simply means a case with oedema, a dry beriberi a case with none, or where the oedema has gone, the resultant paralysis and wasting of the limbs being then well seen.

Rudimentary cases (Larval or ambulatory cases).—Such are due to a limited failure of vitamin. There may be some numbness in the legs, with some patchy anaesthesia and diminution of knee-jerks, all of which symptoms quickly disappear if a more varied diet be given. Such cases, however, give the warning, that if the vitamin deficiency is kept up, more serious phenomena will follow.

Ordinary beriberi.—Prodromata such as pins and needles in the limbs, tired feelings in the muscles and heaviness in the limbs generally usher in the disease. These gradually increase, until the limbs become completely paralysed and further movements become impossible. The knee-jerks, first exaggerated, are then lost, and varying grades of oedema, from a little on the tibiae, to extreme grades where the patient is waterlogged and bloated with fluid, are seen. The sensory nerves are also affected, hyperaesthetic and anaesthetic patches being found at different parts of the limbs and trunk. Shortness of breath and marked dyspnoea generally now appear, indicating

an involvement of the cardiac nerves. The patient is very liable to die suddenly of heart failure at this stage, largely depending on what sort of attention he receives. There is no fever throughout the disease. Finally, if recovery take place, the fluid gradually becomes absorbed, and then the atrophy of the muscles becomes very evident (dry beriberi). The degree of recovery will be in inverse proportion to the amount of nerve destruction. The nerves very slowly regenerate, and as a result the muscles improve in tone until finally complete recovery takes place—this, however, often taking 3, 4, or 6 months for completion.

The heart is dilated to the right, with engorgement of the veins in the neck; the long and short pauses are more or less equalised (equal spacing of the sounds); systolic murmurs are present, and the second sound is generally reduplicated. The pulse is rapid and of low tension. The urine is free from albumin, and there is nothing characteristic in the blood.

Acute pernicious forms.—The patient is seized suddenly, with few or no premonitory warnings, there is great cardiac distress with cyanosis, gasping for breath, coldness of the extremities, and death takes place with great rapidity.

Diagnosis.—This has to be made from all the other forms of multiple peripheral neuritis and in white people is by no means easy. When many cases are occurring amongst natives, whose food is known to be deficient, and if no arsenical or other poison can be incriminated, the diagnosis of beriberi may be made with safety.

Prognosis.—This depends almost entirely on whether the patient can be treated properly or not. If taken quickly into hospital, and surviving the first few days, the chances of recovery are quite good. On the other hand, with no attention and continuing to take the improper diet, the patient will certainly die. The acute pernicious cases all die. Vomiting is always a symptom of very grave significance, and, if severe, indicates a fatal termination.

Treatment.—Since the discovery was made that the disease is purely a deficiency one, great progress has been made in prophylactic measures to control it. The complaint has been stamped out of the jails, asylums and other government institutions in the Federated Malay States simply by changing the diet and giving a parboiled or cured rice, i.e. a rice that has been boiled and dried before husking, instead of a highly polished one.

A patient suffering from beriberi must be placed in bed and not allowed to sit up suddenly. If the condition be serious, amyl nitrite may first be given and small doses of digitalis; venesection may be performed if the right heart be greatly engorged. After the first few days, a dry diet rich in vitamins (eggs, yeast, milk, heart muscle, etc.) should be given. The symptoms will then gradually but slowly improve. Finally, when all acute signs have disappeared, massage and electricity to the limbs will help to restore the muscles to their former tone.

Infantile form.—Recently a form of beriberi occurring in infants has been described. It is common in some of the Pacific Islands. It usually attacks infants fed by the breast by mothers who are poorly nourished. Cessation of breast-feeding and the intake of rice bran on the part of the infant are recommended.

EPIDEMIC DROPSY

Definition.—A peculiar febrile condition, associated with dropsy, vomiting, diarrhoea, skin rashes and anæmia.

Ætiology.—The disease has been described from Calcutta during the cold weather and in Mauritius. Apparently similar conditions have also been met with in other parts of India. Cases have been seen in London by the writer amongst the native crews of steamers coming from India. Both sexes are liable to the disease, children less than adults. The exact cause is unknown, but it is believed to be a disease *sui generis*. It is probably a deficiency disease, or belongs to that group of maladies (Greig).

Pathology.—Effusions into the serous cavities have been observed at autopsy. Otherwise there is nothing special to note.

Symptoms.—The fever is of a remittent type and may precede or be present with the second symptom, namely, dropsy. This begins on the legs, and may spread all over the body. Diarrhoea and vomiting may also occur and pain and aching in the muscles and joints. The exanthem is of an erythematous nature, appearing as a rule after the œdema, and lasting 12 days. The heart shows disturbance of its rhythm with murmurs, and dyspnoea; and finally anæmia results. Scorbutic symptoms sometimes are superadded. The knee-jerks may be present.

Diagnosis.—This has to be made from beriberi, which it resembles in some ways.

Prognosis.—This varies; the death-rate may be as high as 20 to 40 per cent.

Treatment.—A more generous diet should at once be instituted, *e.g.* more rich in vitamins. Cardiac tonics may be required if the heart show signs of involvement.

PELLAGRA

Synonyms.—Mal de la Rosa; Mal del Sole; Maidismus; Malattia della Miseria, etc.

Definition.—Pellagra (pelle, the skin; agra, rough) is a chronic, non-contagious disease of the poor, associated in some way with maize, and running its course with gastric and intestinal symptoms, nervous and psychical disturbances, together with an exanthem of an erythematous nature.

Ætiology.—The disease prevails endemically in Europe, Africa and America. It is very common in Italy, Roumania, Spain, Egypt and in the Southern States of the U.S.A. It also occurs in the West India Islands. Any race is subject to the disease if the conditions be suitable for its production. Children suffer as well as adults; males and females are equally liable. The disease occurs amongst the poor, and at one time was thought to be due to eating diseased maize. The most recent view as to its causation is that it is a deficiency disease—a protein deficiency; races who subsist on maize alone as their standard food receiving a deficient supply of some protein, and so becoming prone to acquire the disease. Goldberger and Wheeler's experimental work in America strongly supports this view. Sambon proposed a hypothetical germ, with the sandfly as an intermediate

host, but there is little or no proof of this, and the theory has recently fallen into disfavour.

Pathology.—The absence of some essential in the food would seem to explain the pathology of the disease. (Compare beriberi, scurvy, rickets, etc.) One of the most important things to be noticed on autopsy is the emaciation and cachexia, the internal organs showing changes associated with such a condition. The heart is small and atrophied. The walls of the stomach and intestines are greatly atrophied and thinned, the mucous membrane showing, in addition, signs of a subacute inflammation. Ulcers are also not uncommon in the colon and rectum. The liver is either of normal size, or may be slightly enlarged and fatty; the spleen and kidneys are small, the parenchyma showing fatty and often also interstitial changes eventuating in a cirrhotic condition. The most important pathological changes are found in the nervous system. According to Scheube, hyperæmia, anæmia and œdema are the conditions most frequently met with in the brain, spinal cord and meninges. Chronic inflammation of the latter also is present. The cord shows sclerosis of the posterior columns, and sometimes of the postero-lateral columns as well. Batten, in material sent by Sandwith from Egypt, found a sclerosis of the posterior columns, and came to the conclusion this was of root origin, the cord changes being secondary. These changes indicate a widespread disease of the spinal cord, being in many ways similar to those found in ergotism and lathyrism. The peripheral nerves do not suffer.

Symptoms.—The incubation period is unknown. The duration of the disease is from 5 to 15 years or more. The course of the malady is distinguished by definite attacks alternating with periods of amelioration, the exacerbations occurring in the spring of the year. Premonitory symptoms, such as giddiness, loss of appetite, and general debility, may usher in the disease. The fully developed condition may be dealt with under three headings. (1) The first attack, consisting of stomacheic and intestinal symptoms, accompanied mostly with an exanthem. (2) Subsequent attacks in which the nervous disorders become more prominent, with serious cerebro-spinal symptoms. (3) The stage of cachexia and marasmus. The three chief systems affected, therefore, are the alimentary, integumentary and nervous. In the first, the appetite is lost, thirst is present, with pain and a feeling of discomfort in the epigastrium, and with eructations and flatulence. Constipation or diarrhœa may occur early; the latter is an invariable accompaniment in the later stages, and with ulceration the stools may contain blood and mucus. The tongue becomes bare, its epithelium being partly or entirely lost (compare Sprue). In the advanced cases it is raw-looking, a similar change often involving the pharynx. The gums may resemble scurvy and the teeth may be decayed.

The changes in the skin have given the name to the disease; they are of less importance than the alimentary and nervous. They usually appear simultaneously with the gastro-intestinal ones, and first appear during the spring months, when the sun is gaining power; they fade away in summer, only, however, to appear again with increased intensity next spring. The distribution is on the back of the hands and forearms, dorsum of the feet, face, neck and upper part of chest, the parts, in short, uncovered by clothing and therefore directly exposed to the sun's rays. The nature of the lesion

is an erythema, first resembling a severe sunburn, with redness, swelling and tension of the skin; sometimes itching and burning and small blebs also occur. Later a deeper dermatitis appears, and in the next year desquamation and exfoliation. As years go on, some pigment and thickening are left, until, finally, a chronic atrophy appears over the affected areas, which become wrinkled, thin, and no longer elastic.

Headaches, pains in the back, neuralgias and vague sensations of weight, pressure or fullness about the head have been observed. The intellectual functions soon become affected, the patient becoming sad, stupid, depressed and sleepless. Paralyzes of various sorts are seen, tremors of the arms and tongue, cramps and wasting of the muscles in the paralysed areas with spasticity and ataxy. The electrical reactions of the muscles are usually preserved. Abnormal sensations and vasomotor and trophic changes are usually present. The knee-jerks are at first exaggerated, and later disappear. Hearing and smell do not suffer, but weakness of vision, hemianopia, diplopia, photophobia are encountered. Mental disorders generally end the picture, melancholia or mania requiring detention in an asylum. Institutions of that nature in countries where pellagra is rife are full of such sufferers.

The other systems may or may not show symptoms. There may be fever during the course of the disease, there is retardation of growth in children, emaciation in adults, and sexual desire is lost.

Diagnosis.—The characteristic distribution of the skin lesions betrays the disease. In some rare cases the cutaneous lesions are absent—pellagra sine pellagra.

Prognosis.—This is not good; large numbers of pellagrins eventually die in the lunatic asylums. The disease is very chronic, lasting even up to 20 years.

Treatment.—Attention should be given to the diet amongst the poor; maize should not form the sole component of the diet; other articles must be added. A generous and varied diet rich in protein must be given—plenty of meat, milk and eggs. Goldberger recommends dried yeast, in doses of 15 to 30 grm. daily, in syrup, and this may be added to the diet. Arsenic may be given, and is of value. The rest of the treatment is symptomatic.

G. CARMICHAEL LOW.

SECTION VII

DISEASES OF THE ENDOCRINE GLANDS

DISEASES OF THE SUPRARENAL GLANDS

THE suprarenal glands consist of two parts, cortex and medulla. The cortex arises from the same type of cell as the kidney and testis, whilst the medulla is of sympathetic origin. The cortex is composed of a fine connective tissue network, surrounding polyhedral epithelial cells, which are arranged in radial rows for the greater part. Towards the surface the arrangement of the cells suggests an alveolar structure, whilst near the medulla the cells form irregular cylindrical columns. All the cells of the cortex contain coarse granules and lipoid globules. The medulla is composed of chromaffin cells. Scattered throughout the medulla between these cells are many non-medullated nerves and a few ganglion cells. Cells similar to the chromaffin cells occur close to the sympathetic ganglia in various parts, and when arranged in masses are termed paraganglia.

The physiological function of the cortex has not been determined, and has been deduced only from the changes associated with pathological conditions. The cortex is essential to life, for removal inevitably kills the animal: whilst removal of the medulla, provided the cortex is left intact, does not lead to death, but merely to fatigue and muscular weakness. The medulla normally elaborates an active substance, termed epinephrin (the proprietary article is called adrenalin), which is an ortho-dioxyphenyl ethanolmethylamine. This substance is made not only by the medulla of the suprarenal glands, but also by the chromaffin cells scattered along the sympathetic system (paraganglia). The secretion of the chromaffin cells is probably an absolute necessity to life, but sufficient is made by those forming the paraganglia, and therefore removal of the medullæ of the suprarenals does not prove fatal.

There is still very much to be elucidated about the action of all the internal secreting glands, and the tabulation of the conditions associated with morbid changes will probably need modification in the near future.

SUPRARENAL CORTEX

Hypertrophy or Tumour.—Hypertrophy or tumour of the cortices occurring in children has often been associated with precocity of growth and sexual development, along with obesity and anomalous distribution of hair. Thus, a boy of 10 may simulate one of 18, not only in his height, weight, and muscular development, but also because his voice has become deep, hair has grown on the upper lip, axillæ, and pubis, his genitalia have developed, and he has become sexually mature, whilst his interests too are those of a youth of 18 rather than those of a boy of 10. Removal of cortical tumours may lead to the abnormal hair falling and the genitalia regaining normal appearance.

Atrophy.—Atrophy of the cortices is believed to produce a condition of premature senility, impotence, or Addison's disease. This is perhaps dependent upon the degree in which the internal secreting glands are affected when the hormone made by the suprarenal cortex fails to reach them. A boy of 14 may simulate an old man of nearly 70. The subcutaneous fat is absorbed, the skin becomes thin, wrinkled, and loses its elasticity, the body becomes bowed, and the features sharp and aged.

SUPRARENAL MEDULLA

Hypertrophy.—No undoubted cases have been recorded.

Atrophy.—Addison's disease.

ADDISON'S DISEASE

Addison's disease is characterised by pigmentation of the skin and mucous membrane, myasthenia, low blood-pressure, and disturbances of the nervous system and alimentary tract, associated with a lesion of the suprarenal glands.

Ætiology.—Addison's disease is found amongst all races and in all climates. It affects men rather more than women; perhaps syphilis being one of the specific causes may account for this. The disease may occur at any age, but is commonest between 15 and 60.

Pathology.—Histological changes in the suprarenal glands have been observed in about 90 per cent. of cases; and in the remaining 10 per cent. it is within the limits of possibility that chemical methods would have demonstrated lack of efficiency, or perhaps there were pathological changes in the solar plexus which escaped detection. Tuberculosis of the suprarenal glands is the most frequent lesion, the tissue often being found to be caseating. Other changes, all of which are rare, placed in order of frequency, are: (1) A chronic interstitial inflammation, leading to fibrosis, and in the latter the glands may be reduced even to the thickness of paper. (2) Malignant disease rarely leads to Addison's disease, because death occurs before symptoms of the latter develop. (3) Extravasation of blood into the suprarenal glands has been recorded as a cause of Addison's disease.

The heart muscle occasionally degenerates. The skin is pigmented, the pigment being found in the rete Malpighii; patches of pigment also occur in the mucous membrane. The medulla of the suprarenal glands normally elaborates an active substance, termed epinephrin, which is an ortho-dioxyphenylethanolmethylamine. The manufacture of this substance is not confined to the medulla of the adrenals, but is shared by all the chromaffin tissue which is scattered throughout the body. The action of epinephrin is that of a stimulant to the sympathetic system, leading to constriction of blood vessels, rise of blood-pressure, dilatation of coronary arteries, dilatation of bronchial tubes, and to an increase in the quantity of sugar in the blood, occasionally giving rise to glycosuria. The secretion of the suprarenal also has a controlling effect over bone, which is demonstrated by its effect in osteitis deformans and certain forms of osseous new growth. The absence of epinephrin in the circulation may lead to profound changes, not only through disturbance of metabolism, but also by means of modification in the distribution of the blood supply to the different organs. Although the medullary portion of the suprarenal glands elaborates epinephrin, nevertheless it does not seem to be essential to life; perhaps the chromaffin cells in other parts manufacture sufficient to maintain life.

At present the dogmatic statement that Addison's disease is due to disease of the medulla of the suprarenal glands should not be made, for the following reasons: A few cases of what appeared to be typical Addison's disease have been examined by competent pathologists who have found that the histological appearance of the suprarenal glands has been normal. Occasionally the morbid condition has been limited to the cortices, the medullæ having been normal. It is alleged too that removal of a diseased suprarenal gland has led to recovery from Addison's disease.

Symptoms.¹—The patient gradually falls off in general health. He becomes languid and weak, indisposed to either bodily or mental exertion, and the appetite is impaired or completely lost. The whites of the eyes become pearly, and the pulse either small and feeble, or of considerable volume, soft and compressible. The body wastes, without, however, presenting the dry and shrivelled skin and extreme emaciation usually attendant on protracted malignant disease. Slight pain or uneasiness is from time to time referred to the region of the stomach; occasionally there is actual vomiting, which in some cases is urgent and distressing. It is by no means uncommon for the patient to manifest indications of disturbed cerebral circulation. "There is characteristic discoloration of the skin, sufficiently marked, indeed, as generally to have attracted the attention of the patient himself or of the patient's friends. This discoloration pervades the whole surface of the body, but is commonly most manifested on the face, neck, superior extremities, penis and scrotum, and in the flexures of the axillæ and around the navel." The tint is distinctly brownish, similar to that produced by the prolonged administration of arsenic, and easily distinguished from the grey of argyria and hæmochromatosis. "This singular discoloration increases with the advance of the disease; the anæmia, languor, failure of appetite, and feebleness of the heart become aggravated; a dark streak usually appears on the commissure of

¹ Much of the description of the symptoms is taken verbatim from Addison's original description of the disease.

the lips; the body wastes, the pulse becomes smaller and weaker, and without any special complaint of pain or uneasiness the patient at length gradually sinks and expires." The muscles become rapidly fatigued in the majority of cases, and the hand-grip is found to wane in strength after a few contractions at intervals of 2 seconds. The pigmentation is not limited to the skin, but is found also on the mucous membrane of the mouth and vagina. Pigmentation of these areas is rare in any condition other than suprarenal inadequacy. Sometimes small dark spots are observable on the skin; but these by themselves are of little diagnostic value, although they may be confirmatory evidence.

Diagnosis.—The symptoms which suggest suprarenal disease are pigmentation of the skin, myasthenia and low blood-pressure. When all three are present, the diagnosis is simple. Pigmentation may be due to other causes. Perhaps that due to chronic poisoning with arsenic simulates most closely the pigmentation of Addison's disease. When the patient has not received arsenic as a drug, but nevertheless it is thought that the colour of the skin may be due to that metal, chemical examination of the hair will decide whether arsenic has been absorbed, but, of course, a positive result does not permit the assumption that the suprarenal glands are healthy. Pigmentation of the skin may be associated with many tumours and also abnormal conditions of the thyroid, liver and blood. The areas of pigmentation occurring in leucoderma should not lead to any error in diagnosis, provided a complete examination is made. The colour of the skin in bronzed diabetes resembles that of argyria and is of a grey rather than brown colour.

The estimation of the sugar in the blood whilst the patient is taking and retaining an ordinary diet may assist the diagnosis in doubtful cases if it proves to be abnormally low. Hypoglycæmia is far from a constant feature, and even a high sugar content of the blood does not rule out the possibility of suprarenal inadequacy.

Low blood-pressure is one of the causes of myasthenia: perhaps the lowest pressures recorded are due to some temporary change in the activity of the suprarenal and are termed functional; these are not accompanied by any pigmentation. When there is a doubt as to the cause of the low blood-pressure, big doses of dried suprarenal gland should be administered; if these lead to a definite rise of blood-pressure, the probability of suprarenal inadequacy approaches a certainty. Suprarenal inadequacy need not necessarily be due to destruction or atrophy of the suprarenal glands; a transient condition, due perhaps to some toxin elaborated by a pathogenic microbe, such as diphtheria, has been observed. The ergograph records myasthenia and may assist in the diagnosis. A positive result, i.e. a rapid diminution in the height of the contractions, is of considerable value, but the absence of the myasthenic reaction does not permit the exclusion of the disease; the writer has had his hand squeezed a dozen times in succession, each time with sufficient strength to cause pain, by a man who died 3 days later from suprarenal tuberculosis. Nausea and vomiting without any reference to food assist in diagnosis, but frequently these are postponed until towards the end.

Prognosis.—The disease proves fatal in the majority of cases within 5 years. Some few cases become chronic, and a still smaller number recover.

We have seen that tuberculosis of the suprarenals is the commonest lesion, and we know that localised tuberculosis may become quiescent. When recovery occurs, the diagnosis is always questioned; but the writer has seen several cases in which the blood-pressure was distinctly raised by the administration of suprarenal extract, and in which repeated cessation of suprarenal medication has led to the recurrence of symptoms and necessitated a return to the drug for a period of many years.

Treatment.—Having arrived at the diagnosis of suprarenal inadequacy, an attempt must be made to determine the cause. Syphilis will be recognised by the Wassermann test; if positive, arsenobenzene preparations may be injected intravenously, provided adrenalin in small doses be injected at the same time. Caution should be used in the selection of the dose.

Tuberculosis should be tested for by the many methods at our disposal, and the original test suggested by Koch should be used as a last resort when all other tests have proved negative. If the degeneration of the suprarenal glands be thought to be due to an invasion of the tubercle bacillus, treatment should be on the same lines as that of any other case of localised tuberculosis. Injections of minute doses of tuberculin should be given, starting with a dose of 50.000 mgrm. T.R., and gradually increasing to 100.000 mgrm. if no untoward symptoms arise. No increase above that amount should be attempted. The theory underlying the treatment is not an induction of immunity, but a temporary hyperæmia of the lesion, acting in the same way as a poultice does when applied to a superficial infection. There seems to be little doubt that suprarenal extract by the mouth is beneficial to the patient, provided it be given in sufficient dosage; 5 grains 3 times a day is almost useless; at least 90 grains should be the daily dose, and even this will not maintain the life of a patient in whom there is progressive disease of the suprarenal. Some advise subsidising this with intramuscular injections of adrenalin. As far as we know, it is only the secretion of the thyroid gland which can be replaced indefinitely by oral administration of the dried tissue.

Operation should be considered whenever any tumour can be felt in the region of the suprarenals; and even when there is no reason to believe that the disease is due to new growth, operation should not be dismissed lightly. Cases have been recorded in which the removal of a diseased suprarenal has been followed by complete recovery.

TUMOURS

Adenomata of the medulla and of the cortex are found frequently at autopsies and have not given rise to any symptoms. Rarely do they grow and invade surrounding tissues.

Malignant tumours of the suprarenal medulla possess the peculiarity of secondary deposits, having the predilection for growing in the bone—often the skull, sternum and vertebrae.

When the growth is in the skull, the appearance of the patient may simulate that of chloroma. The differential diagnosis is easy, because the blood changes characteristic of chloroma are not found.

The diagnosis of suprarenal tumour is difficult, because when the tumour

itself attains a fair size it simulates in many ways malignant disease of the kidney. Examination with X-rays may indicate that the kidney has been displaced downwards, which displacement furnishes evidence of suprarenal neoplasm. Often, as stated above, metastases are recognised before the primary growth produces any local signs. The course of the disease is rapid.

INFECTIONS

The suprarenal glands may be affected by many toxins. Experimentally, congestion, hæmorrhage and infiltration have been produced in animals with toxins of diphtheria, pneumonia, etc. Some observers believe that the fall in blood-pressure in various infections associated with pyrexia is in part due to affection of the chromaffin cells. This infection may be temporary or permanent; when the latter, it leads to a permanent low blood-pressure, and some of the symptoms of Addison's disease, without any pigmentation of the skin.

O. LEYTON.

DISEASES OF THE THYMUS GLAND

The thymus gland is of epithelial origin, arising from two diverticula of the pharynx at the level of the third visceral clefts. A subepithelial lymphoid formation gradually invades and ousts the epithelium, so that finally the gland appears to be a lymphatic gland, with concentric corpuscles (of Hassall), which are all that remain of the epithelium. The relative size of the gland alters greatly; at birth it is about 10 grammes, and may increase up to the age of 2, when it is slowly replaced by fat, surrounding small islands of lymphoid tissue in which the corpuscles of Hassall persist.

The thymus may hypertrophy or atrophy. The conditions arising from these pathological changes have not been studied exhaustively, perhaps because in the past evidence of the changes was usually sought after life was extinct.

HYPERTROPHY OF THE THYMUS

Hypertrophy or enlargement of the thymus is associated with a characteristic stridor and asthma, occasionally leading to sudden death, which has been termed thymic death.

Pathology.—Some have accounted for the symptoms by the mechanical pressure of the thymus upon the trachea and large blood vessels. The trachroscope has demonstrated flattening of the windpipe, and in addition to this the relief arising from intubation with a long tube confirms the view. Whether death results from compression of the trachea, blood vessels or nerves, or is due to laryngeal spasm or myocardial degeneration is of great academic interest; but since the disease is rare, and the arguments lengthy, they must be omitted here.

Symptoms.—Difficulty in breathing is the most obvious symptom, and it may vary from a slight stridor to severe dyspnœa. For convenience of

description, the three grades of severity have been called *stridor*, *asthma*, and *thymic death*; the condition depending upon the extent to which the *enlarged thymus impedes the passage of air through the trachea*.

Stridor due to slight narrowing of the trachea, produced by excessive size of the thymus, is either congenital or develops during the first few days of life. The *stridor* is unlike that due to paralysis of the vocal cords in so far as it is expiratory as well as inspiratory. If the stenosis of the trachea be considerable, there will be retraction of the chest-wall with inspiration. Crying and excitement increase the *stridor*, by increasing the congestion of the thymus. Retraction of the head, too, will aggravate the symptoms, by drawing up the pyramid-shaped thymus into the superior aperture of the thorax, and thus increasing the pressure upon the trachea. The *stridor* diminishes slightly during sleep.

If repeated temporary congestion of an enlarged thymus occur, then attacks of *dyspnœa* simulating *asthma* are produced. These attacks may or may not be preceded by *stridor*. *Asphyxia* may result during the first or any subsequent seizure; rarely has complete recovery been recorded. Sudden death, occurring in a young child without any history of respiratory difficulty, is termed *thymic death* when the post-mortem examination reveals a thymus of more than double the average size. Often *thymic death* occurs during the early stages of the administration of an anæsthetic for some trivial operation. This view recently has been opposed by Dercum and others, who believe that *thymic death* is really due to toxins secreted by the thymic gland overwhelmingly vagotonic in action, leading to cardiac arrest.

Diagnosis.—Now that operative procedure is becoming more frequent in the alleviation of *thymic dyspnœa*, the accuracy of diagnosis is increasing in importance. Intubation with short and long tubes offers the most rapid and most accurate method of arriving at a differential diagnosis. Malformation of the larynx, giving rise to *dyspnœa*, will be relieved by intubation with a short tube; long tube intubation will remove the *stridor* due to pressure of the thymus upon the trachea, but will not alter that due to obstruction of the bronchi or lower end of the trachea. Since the size of the thymus gland can be determined with ease by radiography, perhaps it would be wise to replace the ritual of cardiac auscultation by an X-ray examination of the thymus before the administration of an anæsthetic to a young child.

Prognosis.—We are not in the possession of data upon which we can base prognosis. Intercurrent disease often proves fatal. Probably some number of cases are not recognised, and recover without treatment.

Treatment.—When the thymus is enlarged to an extent that makes *asphyxia* probable, the advisability of operation and removal of the thymus must be considered without delay. Previous to operation, intubation with a long tube should be performed, as otherwise the operation may end instead of *save life*.

If an operation is considered unnecessary, treatment with X-rays may lead to atrophy of the thymus. All precautions should be taken to prevent burning and too rapid disintegration of tissue. During the period of treatment the child must be guarded from everything which may lead to congestion of the thymus or compression of the trachea. In order to prevent excitement and incidental infection, the patient should be kept in bed and all visitors excluded. Baths should be avoided. In no circumstances should

the child be allowed to lie on the knees of the nurse with the head hanging back; retraction of the head must be avoided, if necessary by means of an instrument. As soon as evidence has shown that the thymus has shrunk, a quiet outdoor life is indicated, and no exertion should be permitted.

In cases in which there is a history of syphilis, it is advisable to submit the blood to a Wassermann test, and, if positive, treatment by inunctions of mercury should be adopted. The danger of intravenous injection of arsenobenzene in status lymphaticus is far from negligible.

TUMOURS OF THE THYMUS

Benign and malignant tumours have been described, but both are rare, the former being the less frequent. The benign are lipomata, fibromata, and dermoid cysts; the malignant are carcinoma, sarcoma, and lymphosarcoma. All give rise to similar symptoms, due to pressure in the upper mediastinum. This pressure causes stridulous breathing, difficulty in swallowing, and sometimes affects the cardiac rhythm. Diagnosis is assisted by a radiograph. Treatment consists in exposure to X-rays, or to the action of radium or radon.

THYMITIS

Acute inflammation of the thymus may occur, associated with infection of the surrounding tissues. It is doubtful whether there are any cases recorded in which the condition was of primary origin.

O. LEYTON.

DISEASES OF THE THYROID GLAND

It is to be observed that the thyroid gland is not symmetrically applied to the larynx and trachea: the right lobe is nearer the surface, whilst the left lobe is bounded by the larynx and trachea on the one side and the œsophagus on the other.

The gland consists of a number of vesicles, lined by cubical cells. The vesicles contain colloid substance, presumably secreted by the lining cells. In the resting gland the vesicles are full of colloid. In the active gland the vesicles are irregular, and only a small amount of colloid is present, whilst the cells tend to become columnar in shape. The function of the gland is to prepare thyroxin. It is alleged that the daily consumption of this substance is between $\frac{1}{2}$ and 1 milligramme. Thyroxin contains 67 per cent. iodine, and a shortage of that element diminishes its production. The functional activity of the normal gland differs at different times of the year, the iodine content rising and falling coincidentally.

In hyperthyroidism not only does the gland become enlarged, but microscopically the appearance of the gland suggests activity. The cells lining the irregular vesicles are larger and more columnar in shape, and

may occur in layers two or three deep. Amongst these cells mitotic figures may be seen, showing that there is an abnormal rate of multiplication of the cells. The amount of colloid varies. Usually it is diminished, but that is not characteristic, since the normal thyroid passes through phases of secretion, storing, and absorption of colloid.

HYPERTHYROIDISM

Synonyms.—Exophthalmic Goitre; Parry's Disease; Graves' Disease; Basedow's Disease.

Definition.—A condition due to abnormal secretion of the thyroid gland, usually associated with an increase in the size of the gland, protuberance of the eyes, loss of weight, fine tremor of the hands, palpitation and rapid action of the heart, and general nervous irritability.

Ætiology.—The condition occurs amongst civilised races, but is commoner in warm climates than in cold. There seems to be a family predisposition to disease of the thyroid gland, but no definite evidence that hyperthyroidism is inherited. Different observers record different proportions amongst males and females; apparently 6 females to 1 male are affected by the disease. The onset is most commonly between the ages of 15 and 30.

Pathology.—The pathology of the thyroid gland is perhaps one of the most thorny subjects in medicine. The following will probably have to be modified as further observations are recorded. There is good reason to believe that the most active principle elaborated by the thyroid gland is a derivative of a comparatively simple body, trihydro-triiodo-oxy-beta-indolpropionic acid, named thyroxin by its isolator, but in all probability this is not the only important substance. Since the injection of thyroxin into the blood stream does not cause tachycardia unless amino-acids are in the blood, it is within the limits of possibility that thyroxin is a derivative of a rather more complex body which is less stable. Assuming for the sake of argument that thyroxin is the immediate cause of the symptoms of the disease, we must consider what leads to its production in excess. It has been shown that repeated stimulation of the sympathetic nerves to the thyroid (such as may be arranged by suturing the central end of the phrenic nerve to the peripheral end of the cervical sympathetic) in the cat leads to all the symptoms of thyroid hypersecretion. This shifts the possible cause to that which stimulates the cervical sympathetic. The sympathetic may be stimulated in many ways, amongst others by substances elaborated by the suprarenal glands and by toxins formed in the alimentary tract. If the former be the true cause, then the disease would be of emotional origin (since the suprarenals are stimulated by emotion), whilst if the latter be the explanation the malady should be included amongst diseases due to infection. At the moment, evidence is inconclusive. It has been suggested that exophthalmic goitre should not be termed hyperthyroidism, because the disease is due to qualitative, and not quantitative, change in the secretion; and in support of this view cases have been quoted in which improvement has occurred whilst thyroid has been administered by the mouth. Two explanations of this may be offered—In (1) some cases, through an error of the butcher, thymus was given instead

of thyroid; and (2) when thyroid has been given it may be that some cases of exophthalmic goitre recover in spite of treatment.

Symptoms.—The onset of the malady may be sudden or insidious. Frequently the first symptoms the patient complains of are lassitude and nervous irritability; but since the symptoms may develop in so many directions, it will be wise to consider them under the headings of the different symptoms.

Thyroid gland.—The thyroid gland is usually—but not invariably—enlarged in cases of hyperthyroidism. The right lobe is normally somewhat larger and nearer the skin than the left, and therefore when the enlargement of the two sides is equal, usually the patient first notices that the right side is enlarged. The most rapid way of determining whether the increase in size is accompanied by an increase in activity is by auscultating the gland. On listening to a normal thyroid, or one enlarged by an increase of fibrous tissue, or through the development of cysts, either no sound is heard, or perhaps the heart sounds may be conducted and are heard faintly. In hyperthyroidism, on the other hand, a systolic murmur or a continuous murmur with systolic accentuation, is audible; this varies greatly in character. A diastolic murmur in addition to a systolic has been described, but is very rare. The extent of the increase in size bears no relation to the severity of the condition, occasionally a very large thyroid producing only slightly more than the normal amount of secretion. Huge thyroid glands occur in simple goitre rather than in hyperthyroidism. The gland itself is of normal consistency—soft when compared with a simple goitre.

Heart and circulation.—The condition of the heart and circulation alters during the progress of the disease. Palpitation and rapid action of the heart are often the first symptoms, and the onset of these may be gradual or sudden. The writer has seen the pulse rise to 150 per minute when 30 grains of dried thyroid were administered daily to a patient for a week, due to an error on the part of the dispenser. Tachycardia is due to an increase in the secretion of the thyroid gland. It is true that an injection of thyroxin into an animal does not cause a rapid heart-beat unless amino-acids be present in the blood; but this is no proof that tachycardia in hyperthyroidism is not a direct action of the excess of secretion. The heart-beat may be so forcible as to shake the clothes of the patient and even the head, whilst in cases of even moderate severity the arteries in the neck exhibit pulsation similar to that associated with aortic incompetence. Yet another sign of sudden action of the heart may be noted, namely, capillary pulsation. When the heart has continued to beat between 100 and 200 times per minute for many weeks, cardiac dilatation—perhaps due to fatigue, perhaps to degeneration—occurs, leading to the apex-beat passing outside the mid-clavicular line. When the dilatation is very considerable, relative mitral regurgitation develops and gives rise to the characteristic murmur. This murmur disappears when the heart returns to its normal size. After many months of over-action of the heart, especially when the valves are incompetent, the conductivity of the auriculo-ventricular bundle may become impaired. Changes in the auricular wall are comparatively rare, and auricular fibrillation occurs only in cases of great severity.

Nervous system.—The alteration in the mental condition varies through a wide range, some patients with advanced disease retaining perfect control

over their emotions, whilst others with only slight symptoms need restraint, owing to suicidal and homicidal tendencies. Unrest and excitement are the characteristic changes. The fine tremor of the fingers is similar to that exhibited by the normal individual when intensely excited; along with this, irritability develops and the patient becomes difficult and bad-tempered. Exhilaration and depression may alternate, but the latter is much the commoner.

Eyes.—Exophthalmos—protrusion of the eyes—develops in about 70 per cent. of cases. Usually it is not an early sign. In the majority it is bilateral, but sometimes one side is affected weeks or even months before the other. An excess of fat in the orbit has been recorded at the post-mortems, but the onset may be too rapid to make this a probable explanation. Various symptoms have been associated with exophthalmos, and although they do not add materially to the ease or certainty of diagnosis they are a tradition of medicine. Stellwag's sign—infrequent and incomplete winking; V. Graefe's sign—lids lag behind movement of eyes; Joffroy's sign—on looking towards the ceiling with face inclined downwards, forehead is not wrinkled; Moebius' sign—on making an attempt to focus the eyes upon a very close object in the sagittal plane, one eye turns outwards. Ulceration of the cornea and various infections of the conjunctiva may occur, due to the eyelids supplying insufficient protection.

Metabolism.—One of the most important changes in the body due to hyperthyroidism is the great increase in the rate of combustion of food and tissue, and this may rise to double the normal. If the appetite and absorption be not good, this excessive metabolism will lead to a rapid loss of weight. It seems unlikely that the increase of metabolism is due solely to the general restlessness, rapid heart-beat and activity of glands, because in some cases emaciation is the most striking sign, whilst in others it is very slight. Not only is the metabolism altered in quantity but also in quality; protein is broken up especially quickly, whilst the oxidation of carbohydrates may be modified to so great an extent as to lead to glycosuria.

The blood.—The blood does not present any change characteristic of hyperthyroidism. Occasionally there is an associated chlorosis, and rarely an increase in the percentage of lymphocytes. A relative lymphocytosis is common in disease in which nutrition is impaired, and need not necessarily indicate lymphoid hyperplasia.

Reproductive system.—Loss of sexual power may occur in males; but this is not frequent, and it is associated with many diseases which cause a general loss of strength. In women, menorrhagia is the commonest change in the menstrual function; but in extremely severe cases amenorrhœa occurs, as in other diseases entailing emaciation and anæmia. The mammary glands may persist in size and shape, even when the general loss of fat has been considerable. The effect of pregnancy on the patient suffering from hyperthyroidism seems to be variable; in very severe cases the danger is considerable, whilst sometimes the lesser cases improve during the period of gestation. Since the children of women suffering from this condition are rarely normal, the patient should be advised of the danger run, and act accordingly.

The cutaneous system.—The skin is usually warm and moist. Pigment is increased, especially on the face, in the axillæ, and in the groins. Hair turns grey at an early age, and occasionally falls out.

Alimentary tract.—The appetite is good or may be excessive, and it is only in exceptional cases that the stomach ceases to secrete and contract normally. *Paroxysmal diarrhoea*, without any apparent cause, occurs in about 30 per cent.; its onset is sudden, and recovery occurs without treatment.

Diagnosis.—The difficulty in the diagnosis of hyperthyroidism varies inversely with the severity of the condition. The activity of the thyroid in an emotional individual who lives every moment of the day is greater than in a human mollusc; the argument which made the horse's tail bare may be applied to a discussion on the normal activity of the thyroid.

When the cardinal signs of the disease are present, such as exophthalmos, enlarged thyroid and fine tremor of the hands, the veriest tyro may make the diagnosis—although it must be remembered that some families have exophthalmos without hyperthyroidism, whilst an enlarged thyroid does not necessarily mean an over-active thyroid; again, there are many causes of fine tremor of the hands in addition to hyperthyroidism. The probability of these three signs appearing in the same individual without hyperthyroidism is very small, and if palpitation of the heart be present in addition the diagnosis becomes still more certain.

The cases which are difficult to diagnose are those in which only two signs appear, such as palpitation and emotional disturbance, or emaciation with sleeplessness and mental unrest, or palpitation of the heart with loss of weight. Emaciation for which no adequate cause can be found should always suggest hyperthyroidism. It is absolutely necessary to ascertain whether absorption is normal, because a patient may have a good appetite and eat much nourishing food and yet starve, because the absorption of fat is defective. The estimation of the basal metabolism may supply confirmatory evidence if it be found to be considerably above the average.

Prognosis.—The course of the disease is extremely variable. Slight increase in the activity of the thyroid is extremely common, causing palpitation of the heart, and a condition in which the patient dislikes meeting new people or going to any social function, and is accused of being irritable. When the hands are extended a fine tremor may be noted. When these symptoms are not associated with any definite enlargement of the thyroid gland nor loss in weight, recovery usually occurs within 12 months. If the exophthalmos and increase of the thyroid, along with loss of weight, become definite signs, the disease may take years to run its course. Over 50 per cent. make sufficient recovery to return to work, whilst less than 12 per cent. die from the disease; in the rest, the condition becomes chronic. Relapse is common.

The severity of the disease may be measured by the increased activity of the thyroid rather than by its size, and since the activity of the thyroid modifies the metabolism of the patient the severity may be determined by estimating the basal metabolism. In rare cases this may be found to be more than 80 per cent. above the average.

Treatment.—The treatment of hyperthyroidism may be divided into palliative and curative.

Palliative Treatment.—When possible, the patient should live in a cool, bracing climate, where the excessive metabolism will not lead to the same sense of oppression and discomfort. Apparent alleviation has sometimes followed the administration of substances which are believed to be able to

combine with and neutralise the excessive secretion of the gland, amongst which are the serum of thyroidectomised sheep and the milk of thyroidectomised goats. Quinine hydrobromide in large doses, *i.e.* 10 grains three times a day, may also lead to astonishing improvement. It is unfortunate that not very many individuals can tolerate so large a dosage, and smaller doses are uncertain in their action. The mental irritability of the patient may be treated with bromides, and the excessive perspiration by atropine. Digitalis has been given with the object of controlling palpitation of the heart, but many careful observers have come to the conclusion that it does more harm than good except when auricular fibrillation is present. The patient should be shielded from all annoyance and excitement, and if the condition be severe he should be kept in bed. Application of cold to the skin over the thyroid gland, with the intention of diminishing its activity, may be carried out with Leiter's tubes. Insulin may be given hypodermically in severe cases. As a rule, a slight hyperglycæmia is present in hyperthyroidism, which diminishes the risk of the development of hypoglycæmia; but nevertheless, if the maximum benefit is to be derived from insulin, the sugar in the blood should be determined frequently and the dose of insulin regulated accordingly, because hypoglycæmic symptoms are not easily recognised in hyperthyroidism, since excessive sweating, tremor, and muscular weakness are symptoms characteristic of the disease. Recently the treatment of hyperthyroidism with iodine has been revived. Before adopting this form of treatment, certain ascertained facts should be considered very carefully. In the first place, whilst in a large percentage of cases improvement is to be observed shortly after the commencement of this form of treatment, it is not maintained for any length of time—indeed, after a brief period, the condition of the patient becomes actually worse than before the drug was administered. Secondly, if iodine is employed and after a time stopped, the probability of again obtaining temporary benefit by means of this drug, even if tried after a very considerable interval, is very remote. This peculiarity of the action of iodine is of extreme importance, because when partial thyroidectomy has been decided upon a temporary improvement by means of this drug is of great value in reducing mortality. The dosage varies from 2 to 20 minims in a 5 per cent. solution a day. With regard to diet in hyperthyroidism, the physician finds himself in a somewhat unusual quandary. Based on the fact that thyroxin is a tryptophane iodine compound, some advise restriction of tryptophane intake, and therefore the restriction of protein. Cases have been recorded in which this treatment has been alleged to have done much good. Others have found that a generous allowance of fat in the diet leads to an increased activity of the thyroid, and they therefore suggest the advisability of restricting the fat in the diet and have found that their patients have benefited by this method of treatment. All are agreed that when the thyroid gland is over-active, hyperglycæmia and occasionally glycosuria occur, and therefore at first sight unlimited carbohydrate might seem unwise; but it has been found that the metabolism is unlike that of diabetes mellitus, for in this disease the more carbohydrate given the less is used, while in hyperthyroidism an increase in carbohydrate in the diet is not accompanied by an increase in the excretion of dextrose. One thing is quite certain, namely, that in the case of patients with a high basal metabolism a diet of high energy value is

imperative; and it may further be remarked that when a patient suffering from hyperthyroidism is made fat he usually becomes well.

Curative Treatment.—The form will depend upon the view taken as to the origin of the disease. If it be assumed that hyperthyroidism is the result of stimulation of the thyroid by substances formed in the intestines by a pathogenic microbe, the administration of antiseptics, such as *thymol* carbonate and salol, is indicated, and on this assumption the alleged beneficial effect of quinine compounds may be explained, since they possess bactericidal properties. The evidence of the disease being of definite microbic origin is not sufficiently convincing to justify the recommendation of vaccine therapy, unless it be explained to the patient, or his relatives, that the treatment is still in its experimental stage. At the present time no specific treatment is known which will invariably reduce the activity of the gland to normal. On theoretical grounds it would be expected that a diet containing only a minute trace of iodine would have the desired effect, but in practice this is not found to be the case with any great regularity.

We are not acquainted with any methods of controlling the activity of the thyroid except those just mentioned tentatively, and by section of the sympathetic nerve. This operation, i.e. sympathectomy, is followed by results so variable as to have led to its having been discarded. If the activity of the gland cannot be diminished, the amount of tissue in the over-active gland must be decreased, either by destruction of part of the gland or removal of part of the gland. Before deciding to do either, it must be clearly understood that the activity of the remaining part of the gland may at some future date fall to normal, or even to below normal, and in either case myxœdema will necessarily occur—indeed, this condition, i.e. myxœdema, may ultimately supervene even if none of the gland is destroyed or removed intentionally. Part of the thyroid gland may be destroyed by: (1) The application of *X-rays*; (2) the application of radium; (3) the insertion of radon; (4) ligation of blood vessels; (5) removal of part of the gland (done by means of surgical operation). The choice of which of these five methods should be adopted must depend upon the consideration of a number of data. (1) *X-rays* should be administered with very great care, in order to avoid destroying too much of the gland, which would lead to the early development of hypothyroidism, and also to avoid damaging the skin over the gland. This latter circumstance is especially important in young women, because an *X-ray* burn causes permanent disfigurement. The effect of *X-rays* upon the gland tissue is not immediate, nor is the latent period constant, and therefore considerable judgment and experience are essential for the successful application of this method of treatment. (2) Radium. The effect of radium is more constant than that of *X-rays*. About 1000 mg. hours may be given as the first dose, and this repeated after two months if necessary. Tubes of radium may be placed in the gland itself, and left for sufficient time to lead to the destruction of patches of gland. (3) Radon may be used instead of radium. The quantity of emanation can be estimated accurately, and since it exhausts itself in a comparatively small time it may be left in the thyroid gland. The radon seeds can be introduced through a rather stout exploring needle, and therefore cause only the most minute scars. Further quantities of radon may be inserted at intervals of about 2 months, until sufficient of the gland has been destroyed. (4) Ligation of

the blood vessels does not give sufficiently constant results, and at the present time few surgeons perform this operation. (5) Removal of part of the gland by means of surgical operation. A certain distinguished surgeon who never refuses to operate upon cases of hyperthyroidism, however severe, and in whose hands the mortality from the operation is under 1·5 per cent., states that the indication for operation is the diagnosis of hyperthyroidism. His argument is that immediate operation is almost free from risk, that medical treatment is uncertain, and if unsuccessful permanent damage of the liver and of the heart may supervene. It is difficult to find fault with this statement, but there are few surgeons and nursing homes or hospitals available in which such excellent results are obtainable. The skill and experience of the surgeon and the type of nursing home or hospital are amongst the data to be considered. The economic position of the patient is also of considerable importance. If he must earn his living and support others, it may be advisable for him to submit to operation quite early, because although it is true that nearly 90 per cent. recover without operation, recovery may not take place for several years. With the iodine treatment already referred to under "palliative treatment," only a very small percentage of cases are really unsuitable for operation. In considering whether an operation is indicated or not, it must be remembered that auricular fibrillation which has not responded to digitalis and quinidine therapy may cease after partial thyroidectomy.

HYPOTHYROIDISM

MYXŒDEMA

Definition.—A chronic disease due to insufficiency of the thyroid gland, manifesting itself by changes in the skin and subcutaneous tissues, along with loss of hair, slow metabolism and mental disturbance.

Ætiology.—Complete removal of the thyroid leads to the condition; partial removal sometimes produces a similar result, and always when the remainder of the gland atrophies. The causes of atrophy of the thyroid gland are unknown, and, therefore, all debilitating influences have been held responsible.

Hypothyroidism is often found in several members of one family. It is said to be commoner in cool and temperate zones than in the tropics; but since hypothyroidism is associated with a slow metabolism it would make itself more obvious in a cold climate, and its apparent absence in warm countries may be due to diagnosis being more difficult. Females are affected much more frequently than males, the ratio being 7 : 1. The onset in women is commonly between 40 and 45, i.e. shortly before the menopause. In men the range of years is greater—35 to 50. The thyroid may atrophy in young children and simulate cretinism.

Pathology.—In the majority of cases of hypothyroidism the thyroid is found to be atrophied, and to weigh less than half the average. When it is not smaller in size, histological examination demonstrates that the gland is composed to a great extent of fibrous tissue, and the secreting epithelium is much diminished—in other words, a physiological atrophy has occurred. The increased thickness of the skin is due to an infiltration with

an amorphous substance resembling mucus, but not giving the chemical tests characteristic of mucin. Metabolism is diminished, and qualitative changes may also be noted, including a considerable increase in the tolerance for dextrose.

Symptoms.—The onset of the disease is insidious. Loss of memory and mental hebetude are frequently the first symptoms of which the patient complains. Sometimes pain in the limbs near, but not in, the joints is the symptom causing most trouble, and since the pain has not the characteristic features of rheumatism or neuritis it should suggest to the physician the possibility of hypothyroidism. The skin is dry and thickened, but does not pit on pressure. It is harsh to the touch—not unlike the skin on the forearms of the normal washerwoman, the eyelids are baggy, simulating in appearance a want of tone of the orbicularis muscle such as occurs in insomnia or the œdema of nephritis. The malar flush along with the œdematous face and loss of hair makes a striking picture, which allows immediate diagnosis; but it should be remembered that the diagnosis can be completed and treatment begun long before the typical aspect has developed. The sebaceous glands of the skin become inactive, and the hair dry and brittle and often is shed, not only from the head, but also from the eyebrows. Thickening of the skin results in an alteration in the shape of the limbs, the legs appearing to be œdematous but not pitting on pressure. The hands become clumsy and spade-like.

All symptoms become aggravated in cold weather; this the patient notices, and upon being interrogated will state that the warm weather is preferred. Mental symptoms are very pronounced; in addition to loss of memory, all the mental processes become slow, and it may become impossible for the patient to arrive at any decision.

Speech is slow and rather indistinct; but occasionally when started the patient cannot decide to stop. All the special senses may be affected, partly through thickening of the subcutaneous tissue; this may cause deafness, lack of taste and a blunted sense of smell.

Although the action of the heart seems to be feeble, the blood-pressure is raised and atheroma is common.

Changes in the blood are not characteristic; a mild secondary anæmia may be observed in nearly half the patients; but the anæmia does not approach that which might be expected from the pallor of the skin. Metabolism is slow, and the temperature lower than normal. The appetite is poor, and constipation is frequent. Menstruation is irregular, and menorrhagia far from uncommon; sterility is the rule, but is not invariable.

Diagnosis.—The gradual diminution in the activity of the thyroid as age advances makes it impossible to determine accurately the onset of a condition which starts insidiously. Impairment of energy, of memory and of hair, accompanied by a gain in weight—provided the gain in weight is not due to an accumulation of fluid—suggests hypothyroidism. Occasionally pain near, but not in, the joints is an early sign. The limbs become ungainly, due to thickening of the subcutaneous tissue, but the skin does not pit on pressure. The absence of pitting on pressure assists in the differential diagnosis between myxœdema and renal œdema. The dry skin, the dry hair, the malar flush, surrounded by pale, badly nourished, rather loose skin, make the advanced case recognisable at sight. When doubt exists, the

basal metabolism may be estimated, and if found to be below the normal should be taken as additional evidence of hypothyroidism. Finally, small doses of thyroid gland may be administered tentatively; improvement suggests, but does not prove, hypothyroidism.

Prognosis.—Since the introduction of treatment by the administration of thyroid gland the course of the disease is a rapid return to health; but prior to this the condition became worse, until some intercurrent infection led to death.

Treatment.—Treatment consists in the administration by the mouth of a reliable preparation of dried thyroid gland. Perhaps in the near future thyroxin will be available at a reasonable cost, and then the chief difficulty—namely, the variability of the proportion of active substance in the medicament—will be overcome. The initial dose should be $1\frac{1}{2}$ grains of dried thyroid three times a day, and if this does not lead to any untoward symptoms it should be gradually increased, until palpitation of the heart, tremor, restlessness or sleeplessness ensues. The dose should then be diminished, until these symptoms disappear. The tolerance for dextrose may be used to decide whether the correct dose has been found. If the patient is unable to take 100 grammes of dextrose as a single dose without glycosuria following, the dose of thyroid should be cut down still further. If care be taken to increase the dose slowly, and the patient be warned to lead the life of an invalid until the optimum dose has been established, the risk of any untoward event is almost negligible. The improvement is rapid and complete.

When thyroid extract is badly borne, or there is some other adequate reason for another method of treatment, an operation for thyroid grafts should be considered. If an operation be decided upon, it should be remembered that the grafts must consist of human thyroid which is secreting actively; that the tissue must be absolutely fresh and undamaged; and that it must be introduced into some part of the patient in which it is certain it will not be surrounded by a blood clot. Multiple subcutaneous implantations have given the best results; small but numerous pieces up to 40. The operation will succeed only if the utmost care be taken by the surgeon. When the grafts take they grow, and quite frequently the dose of thyroid by the mouth may be gradually diminished and finally stopped.

CRETINISM

Definition.—Cretin originally meant a small dwarf; but the term cretinism is now reserved for cases of congenital endemic and congenital sporadic thyroid insufficiency.

Ætiology.—Cretinism is endemic in most of the areas in which endemic goitre is found, and as a rule one or both of the parents of a cretin suffer from disease of the thyroid gland, and are either mild cretins or have goitres. The incidence of the disease in different districts must vary greatly, since one authority states females are affected more frequently than males in the proportion of 2:1, while another asserts that the proportion is quite the reverse, namely, 2:5.

Pathology.—The thyroid gland at birth is either absent or atrophied.

When the diminution in its size is not very striking, microscopic examination shows almost complete atrophy of the epithelium. The absence of the thyroid gland causes a general disturbance in nutrition, demonstrating itself in retarded development of bone and delayed ossification. The bones of the limbs are short, thick and often deformed. The skull is prognathic, but variable in size. As age advances the cretin often develops a goitre, which is found to be fibrous or cystic. The pathology of cretinism is debatable. Since the removal of a goitre from a cretin leads to the development of further signs, it seems probable that cretinism is due to insufficiency of the thyroid rather than complete inactivity.

Symptoms.—Cretins rarely grow to 5 feet in height. The body is relatively broad, the legs short and often crooked, the abdomen large and pendulous, the skin hangs loosely, and is thick, harsh and inelastic.

The face of the cretin is prognathic, with a flat nose and large nostrils, and a broad and low forehead, surrounded by thin, dry hair. The tongue is large and the lips thick. The genitals do not develop until after the thirtieth year. The supra-clavicular fossæ appear to be cushioned, due to thickening of the subcutaneous tissue. The mental condition in cretinism is characteristic of want of development. Cretins are apathetic, and possess little or no memory; the more severe cases are unable to talk; and many are deaf, perhaps due to obstruction of the Eustachian tubes.

Diagnosis.—When a child fails to develop either physically or mentally, inefficiency of the thyroid gland should be considered. In order to prevent error in diagnosis, we should remember that there are a number of conditions other than cretinism in which physical development is abnormal; amongst these are rickets, achondroplasia, dwarfism, congenital adiposity and hydrocephalus. The positive signs in cretinism are slow metabolism, as shown by slow pulse, low temperature and cold skin, along with the deposition of fat.

The differential diagnosis between rickets and cretinism should not be difficult, because in the former there is enlargement of the epiphyses, accompanied by profuse sweating, especially at night, and the mental condition, although placid, is not far removed from the normal; in cretinism the bones may be deformed, but the epiphyses are not big, the skin is dry and the mental condition approaches imbecility. The hands, too, are dissimilar; in rickets the hand is beaded, in cretinism spade-like. The shortening of the limbs in achondroplasia is a symptom so definite that there should be little difficulty in distinguishing it from cretinism. Examination of the thyroid may assist; often it cannot be felt, but when distinctly goitrous it clinches the diagnosis. The basal metabolism of cretins is low, but more elaborate apparatus is required than that used for patients of average intelligence. If the signs do not justify a definite diagnosis, recourse may be had to small doses of thyroid gland; a distinct improvement following its use is very suggestive of cretinism.

Prognosis.—Untreated cases remain *in statu quo*; but the immature mind and deformed body become more obvious as age advances. Usually cretins die young, from some intercurrent disease, but occasionally reach the age of 50. If the patient be quite young when the administration of thyroid is begun, all signs may disappear, and a complete cure be effected. The earlier the treatment is commenced, the more satisfactory the result.

Treatment.—Since cretins are usually the offspring of goitrous parents,

the prevention of goitre will prevent cretinism. Goitre seems to depend upon an infected water supply, so indirectly the abolition of cretinism should occur through improving the water supply in the districts in which the disease is endemic.

The administration of dried thyroid gland and the removal of the patient from goitrogenous influence will lead to immense benefit, provided the diagnosis has been made fairly early, and treatment adopted promptly. The size of the dose depends upon the extent of atrophy of the thyroid, and can only be determined by trial. Perhaps the best method of deciding the dose is to increase it until some untoward symptom appears, and then to estimate the basal metabolism of the child; if this latter be far above that of the normal child of the same weight, the amount of thyroid given by the mouth should be diminished until the metabolism falls to normal.

SPORADIC CRETINISM.—This is in every way similar to endemic cretinism.

GOITRE

Definition.—Enlargement of the thyroid gland of a chronic character, not due to new-growth nor associated with symptoms of hyperthyroidism.

Ætiology.—Sporadic cases occur, but the majority are confined to certain districts, in which the condition is found amongst animals as well as man. Most of the places in which goitre is endemic possess one thing in common, namely, a water supply which is not well protected from contamination by human excrement, and also is usually completely devoid of any salts of iodine. It is true that exceptions to this have been recorded, but they are rare. The disease is endemic in many valleys in the mountainous parts of Switzerland, France, Germany and Austria, whilst there are very few foci in Sweden, Norway and Finland. Goitre is commoner amongst women than men, except in endemic areas, where the incidence is equal. Congenital goitre is rare in non-goitrous districts. When it occurs in a locality in which the disease is not endemic, as a rule one of the parents is found to be suffering from the complaint. Goitre usually occurs in childhood and gradually diminishes in frequency after puberty. The actual cause of goitre is not certain, but evidence is accumulating that it occurs in human beings who drink water contaminated by something which does not pass through a porcelain filter. Boiling the water renders it innocuous. These observations suggest, but do not prove, that one of the exciting causes is microbic. Experiments have proved that not only in animals but also in man, an enlargement of the thyroid gland follows the ingestion of the residue on a filter through which goitrogenous water has passed. It has been suggested that goitre belongs to the group of diseases that go by the name of deficiency diseases such as rickets, which can be produced either by depriving an animal of fat-soluble vitamin or sunshine. The similarity between goitre and rickets is considerable, because apparently goitre can be produced either by the contamination of the water or by depriving the individual of a sufficiency of iodine or salts of iodine. Just as the more sunshine an animal is exposed to, the less fat-soluble vitamin is necessary, so too, apparently the greater the contamination of the water with goitrogenous substances the greater the amount of iodine necessary to prevent the disease. This theory explains

why either the filtering or boiling goitrogenous water is necessary, since these two processes modify the toxins, or the administration of iodine or salts of iodine lead to cure. In some, but not all, districts where goitre is endemic, its incidence has been reduced considerably by iodine being added to cooking salt to the extent of 2 to 5 mg. per kilo.

Pathology.—Several types must be described, although it is rare to find an enlarged thyroid quite characteristic of any one.

1. Simple hypertrophy, or so-called parenchymatous goitre, in which there is a general increase in normal thyroid tissue. A section of any part presents the appearance of a normal gland.

2. Colloid goitre, in which (in addition to an increase in the number of follicles) the quantity of colloid is excessive. In this condition the gland may be large, because not only are the follicles increased in number, but also in size.

3. Cystic goitre, due to degeneration of the walls in colloid goitre. The cysts contain colloid.

4. Hæmorrhagic-cystic goitre; as the name implies, hæmorrhages have taken place into the cysts.

5. Fibrous goitre, resulting from inflammatory changes. Calcification is not uncommon.

Temporary enlargement of the thyroid may be produced in a variety of ways, perhaps due to stimulation of the cervical sympathetic and increased activity of the gland. If simple hypertrophy were the only type of goitre, it might be explained on the lines that the organism required the gland to elaborate more of its active principle, perhaps to neutralise some toxin or to modify metabolism. This does not hold, because the simple hypertrophy usually passes on to degeneration.

Symptoms.—The onset may be sudden, but is usually insidious, a very rapid increase in the size of the thyroid suggesting a malignant growth rather than simple goitre. The symptoms are due to the mechanical effect of the gland pressing upon adjacent tissue—the trachea, various nerves (vagus, sympathetic, spinal accessory and recurrent laryngeal), the oesophagus, and perhaps indirectly upon the heart. Dyspnoea is caused by compression of the trachea, the breathing being often worse at night, probably because the recumbent position leads to an increase in the size of the goitrous—in the same way as in the normal—thyroid. Difficulty in swallowing may result from the pressure of a goitre; complete obstruction has been recorded, but this is much more common in malignant disease of the thyroid. Pressure on the veins sufficient to produce cyanosis of the face is noted only when the goitre is very large. It is true, as stated above, that various nerves may be pressed upon and cause symptoms, but this is extremely rare. Pressure upon the vagus may cause an alteration in the frequency of the heart-beat, and interference with the sympathetic will lead to dilatation of the pupil and irregular sweating in the affected side. Irritation of the spinal accessory nerve gives rise to spasm of the trapezius, whilst paralysis of the recurrent laryngeal is a cause of hoarseness. The direct effect of goitre upon the heart is debatable. Much is to be said in favour of the view that when the thyroid is enlarged and the heart's action becomes pathological, this is due to hyperthyroidism, and that the condition should be considered as such and not as simple goitre.

Prognosis.—Goitre is a chronic disease and—since its effects are purely mechanical—is not necessarily progressive, for the size of the goitre often remains stationary. Whatever the cause, we cannot expect goitres of long standing in which there are fibrous or cystic changes to diminish in size rapidly; only recent cases can be cured quickly, and occasionally the “cure” occurs without treatment. Sudden death resulting from hæmorrhage into the thyroid (causing obstruction of the trachea) fortunately is a rare dramatic end.

Treatment.—*Prophylaxis.*—It is not easy to understand how sporadic cases of goitre can be due to the same cause as endemic cases. Experience and experiments have shown that the water from streams and wells which are responsible for the development of goitre is rendered innocuous by boiling. Perhaps a perfect filter will act in the same way as boiling, but no known filter remains perfect for more than a week or two. The essence of prophylaxis, therefore, is the avoidance of water from sources known to possess the toxin, or boiling the water.

The line of treatment adopted will depend upon the view held as to the cause of the disease. If the disease is due to an infection of the alimentary tract, the administration of intestinal antiseptics, such as thymol, may be expected to benefit the patient, especially if combined with inoculations of a vaccine prepared from the organism which is considered to be the cause. Some observers have recorded rapid cures in cases treated in this way, but we must remember that the thyroid often returns to its normal size upon removing the patient from the goitrous district. Iodine has a direct action upon the thyroid, and, as has already been stated, it is necessary to avoid its administration in any form in thyroiditis, because it stimulates the gland's activity. Small doses of iodine lead to shrinking of the goitre, if it be purely hyperplastic. An excess of iodine must be avoided, lest the symptoms of hyperthyroidism be produced. Perhaps the application of potassium iodide ointment, or even painting an area of the skin with tincture of iodine, will lead to a sufficient amount being absorbed. It is not essential to apply the ointment or tincture to the skin over the thyroid. If iodine be given by the mouth, 6 grains of sodium iodide per diem should be the maximum.

When the size of the goitre is so great as to give rise to dyspnoea or difficulty in swallowing, surgical assistance should be sought. The knife of the skilled surgeon leaves a scar which only a keen eye can detect.

TUMOURS OF THE THYROID

Various forms of new-growth of the thyroid have been observed: carcinoma, adeno-carcinoma, scirrhus and sarcoma.

All these growths may remain within the capsule of the thyroid and may give rise to the same symptoms as goitre for months or even years; ultimately either the growth passes beyond the capsule and may cause erosion of the œsophagus or larynx, or metastases develop, not infrequently in bone, and most commonly in the parietal, lower jaw, sternum, pelvis and humerus.

Sometimes the growth in the bone is the first sign noted, and the primary growth may not be found until the autopsy.

The symptoms arising in new-growth are to a large extent mechanical, and are identical with those of a large goitre.

THYROIDITIS

Ætiology.—Exposure to cold or local damage to tissues may predispose to thyroiditis, through diminishing the local resistance to micro-organisms and perhaps to toxins. Thyroiditis may occur in any infection, not only of bacterial origin, such as influenza, cholera, diphtheria, puerperal fever, erysipelas and typhoid, but also of protozoal, such as malaria and syphilis. It may arise, too, during infections of unknown cause, such as rheumatic fever, scarlet fever, measles and small-pox. The condition is commoner during the third and fourth decades than in early or late life. A slightly greater proportion of females than males are affected.

Pathology.—The earliest changes are in the epithelial cells, which may be shed and fill the lumen of the vesicle, the shed cells being rapidly replaced by an increased growth. The colloid may disappear or alter in consistency. Small abscesses may form, either single or multiple.

Symptoms.—The onset of the disease is sudden, like most infections, and is accompanied by chilliness. When the glands swell—which usually takes place on the second day—a sensation of fullness, difficulty in swallowing, and pain passing backwards to the ears and occiput, develop. The thyroid becomes tender. If the gland becomes very swollen, the mechanical effect of pressure may lead to difficulty in deglutition and to partial obstruction in the veins, resulting in congestion of the face.

Prognosis.—Simple thyroiditis lasts but a few days. Suppurative thyroiditis varies in its course, death occasionally resulting from asphyxia.

Treatment.—Iodine in every form should be avoided. Sedatives and hypnotics may be given with advantage. The formation of abscesses must be borne in mind, and surgical treatment adopted if evidence can be found by the exploring needle.

INFECTIONS OF THE THYROID GLAND

Tuberculosis of the thyroid gland is far from common. Tubercles may be found in the majority of cases of miliary tuberculosis, but they are present in only 5 per cent. of those dying from chronic tuberculosis.

Tuberculous granuloma in the thyroid is rare, and indistinguishable from new growth, until it breaks down and forms a cold abscess.

During the secondary stage of syphilis the thyroid is enlarged in about 50 per cent.: the enlargement is painless, and, therefore, attention is not drawn to it. When gummata form in the thyroid the symptoms simulate those of new growth, and, therefore, in all cases of rapid enlargement the patient's blood should be submitted to the Wassermann test.

Actinomycoosis, echinococcus and *Schizotrypanum cruzi* may invade the thyroid, but the first two are rare, while the last is confined to South America.

O. LEYTON.

DISEASES OF THE PARATHYROID GLANDS

Removal of the parathyroid glands from certain animals leads to a definite series of symptoms, the most striking of which are tremors, rigidity of the

hind limbs, an uncertain spastic gait, muscular weakness, paresis of muscles of mastication, along with convulsions. There is often loss of appetite and vomiting, and rapid and violent beating of the heart. The urine becomes scanty. These symptoms have been attributed to the formation of an excess of guanidine and methyl guanidine, for two reasons. These substances are found in the urine of animals from which the parathyroid glands have been removed; and also because the injection of these substances may produce tetany, or aggravate tetany when it has already occurred. The fact that after ablation of the parathyroid glands in dogs the concentrations of urea and non-protein nitrogen in the blood run parallel, whilst after the injection of guanidine into normal dogs in sufficient quantity to produce symptoms the non-protein nitrogen increases to a greater extent than the urea concentration, is considered by some to be conclusive proof that guanidine and methyl guanidine do not explain completely the symptoms following parathyroidectomy.

HYPERTROPHY	{ Osteitis fibrosa, and probably other diseases of the bones.
REMOVAL, DESTRUCTION, OR ATROPHY	{ Tetany, and a syndrome associated with changes in the calcium content of the blood.

PARATHYROID INSUFFICIENCY

Symptoms.—The patient suffers from uncontrollable restlessness, inability to relax muscles and to sleep quietly. Spasms of almost any muscles may occur, sometimes accompanied by pain so severe as to call for the injection of morphine if active parathyroid extract be not available. This increased irritability of the nervous system, associated with spontaneous attacks of spasms, has been termed tetany. In tetany there is an increased response to excitation of the motor nerves with the constant current, whilst pressure on certain nerves leads to unusual results. Pressure on the nerves in the bicipital sulcus makes the hand and forearm adopt a peculiar attitude: the fingers and thumb appear to be arranged for the hand to pass through the smallest possible aperture. Tapping the facial nerve causes contraction of the muscles on the same side of the face. Carpo-pedal spasm is usually present in well developed tetany.

Tetany may arise from a series of causes, but it is usually associated with a too low calcium content of the blood.

Treatment.—Tetany is improved by increasing the calcium in the blood. This can be brought about within an hour by the subcutaneous injection of the active principle of the parathyroid glands, or more slowly by the administration of soluble calcium salts. When the calcium content of the blood rises to normal, symptoms subside and the patient returns to health. In those cases in which the parathyroid glands have been removed by the surgeon, or destruction has occurred by hæmorrhage into them or in any other way, repeated injections of parathyroid hormone must be given indefinitely. There seems to be some doubt as to whether the present day active extract contains all the essentials, since it has been stated that even if the injections be given in increasing quantities, it is not possible to prolong

for more than a few years the life of the patient who has been deprived of all his parathyroids.

O. LEYTON.

DISEASES OF THE PINEAL GLAND

The function of the pineal gland, which normally atrophies at puberty, is not known. According to some observers, experimental removal of the gland from young animals leads to hypertrophy of the testes, whilst others assert that "no sexual precocity or indolence, no adiposity or emaciation, no somatic or mental precocity or retardation follows." *Hypoplasia* of the gland has been recorded in two cases. In one there was precocious development of the mammary glands, and in the other sexual infantilism. *Hypertrophy* of the gland is not known, but tumours of the gland occur occasionally, and in 14 per cent. there is associated precocious sexual development, along with overgrowth or adiposity. The symptoms of pineal tumour are those of intracranial pressure, viz. headache, nausea, choked disc, drowsiness, and mental changes. The signs which occur most frequently are paralysis for upward movement of the eyes, diplopia, abducens paralysis, ptosis, nystagmus, and the absence of pupillary reaction to light. The only hope of benefiting a patient with a pineal tumour is by operation; but even in the most skilled hands the mortality has been very high. *Atrophy*: pineal gland has been given to children who are defective in mind and in muscle, but the evidence of benefit arising therefrom is inconclusive, though perhaps sufficiently encouraging for further investigation.

O. LEYTON.

DISEASES OF THE PITUITARY GLAND

The pituitary gland consists of two main parts--the anterior lobe and the posterior lobe. The anterior lobe possesses the characteristic appearance of a gland with an internal secretion, the acini containing a colloid material; this part of the gland secretes into the blood stream. The posterior lobe (*pars nervosa*), with its epithelial investment (*pars intermedia*), is of nervous origin, and secretes into the cerebro-spinal fluid.

The two parts of the gland are of different origin and possess completely different functions, and therefore morbid conditions of the two parts give rise to different symptoms.

ANTERIOR LOBE	{	Hypertrophy :	Acromegaly‡
		Atrophy :	(?) Dwarfism.
POSTERIOR LOBE	{	Hypertrophy	Hyperglycæmia.
			(?) Hyperpiesis.
	{	Atrophy	Obesity.
			Dercum's disease.
			Fröhlich's syndrome.
			Diabetes insipidus.

1. ACROMEGALY

Definition.—As the name implies, acromegaly is a condition in which the hands and feet grow abnormally; the whole of the bony frame also increases in size—but the size of the extremities is the most obvious.

Ætiology.—The disease has been reported amongst many races in various parts of the globe. The type of acromegaly which is to be considered as a disease is not hereditary, although a slightly over-active pituitary may be a peculiarity of some families in whom height and heavy jawbone are distinguishing features. The onset may be at any age, but in males is most common between the ages of 20 and 30, while females are often older. Males and females are affected in equal numbers.

Pathology.—Acromegaly is due to hypersecretion of the anterior lobe of the pituitary gland, sometimes due to overgrowth—which may be demonstrated with the X-rays by the increase in the size of the sella turcica. The overgrowth is usually adenomatous; when malignant the growth may be too rapid to permit life to be prolonged sufficiently for the symptoms of the disease to develop. Occasionally there is no demonstrable increase in the size of the pituitary gland; but this is not proof of the gland secreting only a normal quantity. A similar condition exists in distinct hyperthyroidism without any enlargement of the thyroid gland.

Symptoms.—The onset is usually gradual. The first symptom may be bitemporal headache, with the sensation that the head will burst. Lassitude may make it impossible for the patient to carry out his usual work. The sexual functions cease early in the disease. The hands and feet grow unduly, necessitating larger sizes of gloves and boots, the height increases, and the general aspect of the patient so alters that he becomes quite unrecognisable by those friends who have not seen him for a long time. The lower jaw becomes enlarged in nearly all cases, whilst the vertebral column shows changes in 86 per cent. of cases, most commonly cervico-dorsal kyphosis. The bones of the face grow more rapidly than those of the head, so that the hypertrophied ears appear to be placed too far back. The supra-orbital ridges become prominent, leading to a profile characteristic of acromegaly. The nose broadens and becomes coarse, the lips become thick, and the lower lip often everts, and the tongue is too large for the mouth. The skin becomes thick and warty, and the hair coarse and profuse.

Diminution in the fields of vision is very common, and occasionally there is photophobia. Hemianopia may result from partial destruction of the optic nerves, due to pressure of the tumour, and if the growth be considerable the olfactory lobe may be interfered with and the sense of smell impaired; but this is comparatively rare. Transient glycosuria may be present. The sugar appears in the urine only whilst the disease is developing; when the gland has reached a stationary condition the sugar tolerance is above the normal—in some cases 400 grammes of dextrose may be administered as a single dose without sugar appearing in the urine. The blood sugar is rarely above normal (0·12 per cent.). The blood-pressure is abnormally low—systolic pressure with the Riva Rocci apparatus 90 to 100 mm. Hg. The temperature is often about 1° F. below the average.

Diagnosis.—The conditions which may be mistaken for acromegaly are osteitis deformans and pulmonary osteo-arthritis. As a rule, in

osteitis deformans the shafts of the long bones are affected and there is no increase in stature. When difficulty arises, two observations quite unconnected with growth or appearance may prove of value: (1) As stated above, the tolerance for dextrose is often increased. If 100 grammes of dextrose be taken at a single dose by a normal individual, sugar is not excreted in the urine, but 100 grammes is near the limit; and if this be increased to 150 grammes glycosuria results in a large percentage of individuals, whilst in many acromegalics the tolerance is above 200 grammes. (2) The temperature of acromegalics is 97° F., and the injection of extract of anterior lobe leads to a thermic reaction, 0.4 grain causing a rise of temperature to 100° F.

Prognosis.—The course of the disease is extremely variable. Often the pituitary, after more than doubling its size, ceases to grow, and then the patient may live 20 years or more. A fatal termination results from the pituitary enlargement involving other tissues in the skull.

Treatment.—If acromegaly be due to increased secretion of the anterior lobe of the pituitary gland, it is difficult to understand how administration of pituitary gland in any form can lead to benefit; but, nevertheless, some number of cases are recorded in which the patient has been satisfied that the dried gland taken by the mouth has led to improvement. When the headache is intense, and makes life not worth living, or the vision is becoming more and more impaired, operative procedure should be considered. The operation is not without risk, and also it should not be forgotten that in many cases the arrest of the disease is spontaneous.

2. ADIPOSIS DOLOROSA

Synonym.—Dercum's Disease.

Definition.—A disease characterised by the development of masses of fat, which are painful and tender, accompanied by asthenia and psychic disturbance.

Ætiology.—The affection may occur at any age, but most commonly between the ages of 20 and 40 years. Females suffer from this disease much more frequently than males.

Pathology.—Dercum at one time was under the impression that the condition was due solely to an altered activity of the thyroid gland; but in several recent autopsies of patients suffering from this disease morbid conditions of the pituitary gland have been found, making it probable that the primary lesion is in the pituitary gland.

Symptoms.—The patient complains of being very depressed and having little control over the emotions. She will weep without any provocation, and on being asked why she is weeping will reply that she does not know, but cannot help it. The pain in the fatty lumps may be severe; but usually it is not sufficient to account for the mental alteration. Lumps of fat develop in the skin. The distribution varies, but usually they may be found on the posterior aspect of the upper part of the upper arm, and on the flexor surface of the lower part of the thighs. Sometimes the fat is more evenly distributed, and occasionally the lower limbs escape altogether.

Prognosis.—The disease need not shorten life, but the excess of fat seems

to diminish resistance, and the patient usually dies from some intercurrent disease.

Treatment.--As the patients have no initiative, and seem to make a habit of spending the time contemplating their misery, it is advisable to insist on their leading social lives. Injections of an active extract of pituitary gland should be given whenever possible, since the effect is much more certain than oral administration, together with thyroid gland by the mouth. Under this treatment, diminution of fat occurs frequently, a case under observation having fallen from 20 stone to 16 stone in 6 months. To obtain this result, a suitable diet should also be adopted, and perhaps the under-nutrition is most easily attained by ordering the patient to eat raw food only. The improvement in the mental condition is not so great as in that of the body. When thrombosis occurs in the veins of the lipomata, rest must be ordered along with a drug, such as sodium citrate, which diminishes the coagulability of the blood by reducing the amount of calcium absorbed.

3. DYSTROPHIA ADIPOSO-GENITALIS (FRÖHLICH'S SYNDROME)

Hypopituitarism in the adult leads to adiposis dolorosa (Dercum's disease), whilst the same change in the pituitary gland occurring in early life stops the normal development of the reproductive organs, and then the symptoms of castration become added to those of hypopituitarism.

Pathology.--The disease is the result of diminished activity of the pituitary gland, due either to atrophy of that gland or destruction by some tumour originating in it or in the immediate vicinity.

Symptoms.--The chief symptom is an increase in adipose tissue, which may be distributed in any way, along with an infantile shape and size of the external and internal organs of reproduction. In women menstruation is either absent or irregular. The other symptoms due to pituitary change, such as polyuria, increased tolerance for dextrose and depressed temperature, may or may not be present.

Prognosis.--This depends upon the cause of the hypopituitarism. When produced by pressure of a malignant growth, the disease runs a rapid course; if, on the other hand, destruction be due to a cyst or some other non-malignant tumour the condition need not necessarily shorten life.

Treatment.--Treatment is on the same lines as that of adiposis dolorosa. If there be definite evidence of a tumour, which radiograms taken at intervals show is increasing in size, operation should be performed, for although the risk is great it is justifiable when it offers the only chance of prolonging life.

4. DIABETES INSIPIDUS

Definition.--An increase in the secretion of urine, without any distinct increase of the normal solid matters or the presence of any abnormal constituents.

Ætiology.--It is alleged that the disease is commoner amongst males than females in proportion of 2 to 1; this may be due to the fact that

syphilitic meningitis occasionally damages the pituitary, and syphilis is commoner amongst men than women. Some cases which appeared to be hereditary have been recorded.

Pathology.—The disease is due to some interference with the internal secretion of the posterior part of the pituitary gland, sometimes the result of trauma, sometimes to a tumour in the immediate neighbourhood which may interfere with the blood supply. Occasionally at the autopsy the pituitary gland itself does not present any morbid change, whilst a lesion is found in the mid-brain. It seems probable that it is this type of case which fails to respond to treatment with pituitary extract.

Symptoms.—The onset may be sudden, and timed as following some emotional disturbance, but more frequently it develops slowly. The symptoms are polyuria and intense thirst. The quantity of urine secreted may rise to 20 pints or more in the 24 hours. The colour is very pale yellow, sometimes with a faint greenish or bluish tint. The specific gravity is only slightly above that of distilled water.

The polyuria leads to disturbed sleep, and in spite of a moderate appetite the patient loses weight and becomes restless and depressed.

Course.—The course of the disease is usually protracted. The patient dies either from some intercurrent infection, or emaciation becomes extreme and the patient develops coma before death, a coma dissimilar to that produced by fat intoxication in diabetes mellitus.

Diagnosis.—The differential diagnosis between diabetes insipidus and diabetes mellitus depends upon the presence of sugar in the urine in the latter disease, provided a normal diet is given. Polyuria occurs in chronic interstitial nephritis, but usually there is a trace of albumin in the urine, and often a hypertrophied heart and raised blood-pressure. When doubt exists, the excretion of phenolsulphone-phthalein may be used as a test. The writer has seen a few cases of polyuria which have been associated with and due to the development of a habit of drinking much coffee. The polyuria ceased when the coffee was reduced. So-called hysterical polyuria may simulate diabetes insipidus for a time. In the former, the polyuria is usually of short duration and is accompanied by other manifestations, but in our opinion there is grave doubt whether this condition is not the result of some temporary alteration in the activity of the pituitary gland. A radiogram of the skull shows a change in the sella turcica in a small percentage of cases of diabetes insipidus. When present it is good diagnostic evidence; the absence of this change may be disregarded.

Treatment.—Treatment must depend upon the cause of the disease. Injections of extract of the posterior lobe control the polyuria for a number of hours—often about 6, but repeated injections do not cure, but seem to supply the material which the gland fails to elaborate, and alleviate symptoms. The extract of the posterior lobe of the pituitary gland contains substances which have several actions. One of the substances causes contraction of the uterus and is used by obstetric physicians for that purpose. A second substance, called vasopressin, causes contraction of plain muscle and leads to a great rise of blood-pressure. It has been asserted that this latter substance also controls the cells of the kidneys and prevents diuresis in diabetes insipidus. But there are some reasons for believing that the substance which acts upon the blood vessels is not identical with that which acts upon the

kidneys. Until the substance controlling diuresis has been isolated, it will be wise for the physician to try various extracts of pituitary, in order to ascertain which of these controls the diuresis for the maximum time in each case. As the *Spirochaeta pallida* is one of the causes of destruction of the gland, the Wassermann test applied to blood and cerebro-spinal fluid should be carried out without delay, and, if positive, appropriate anti-syphilitic treatment administered. Cases have improved while on large doses of thyroid extract. The dependence of the pituitary upon the thyroid remains an unknown factor, and perhaps it is wise to try the effect of thyroid by the mouth when it is impossible to carry out regular hypodermic injections of pituitary extract. The majority of observers find pituitary extract administered by the mouth is useless. It is scarcely necessary to add that any restriction of the amount of fluid given to the patient is an abuse of authority.

O. LEYTON.

ABNORMAL GROWTH

Growth depends upon many factors, only a certain number of which are known at present. Although Lunin, a physiologist, stated in 1881 that casein, carbohydrates, certain fats, salts and water were insufficient to maintain healthy life, he was a prophet crying in the wilderness, and it was only later that the accessory factors in food-stuffs were recognised as essential. These substances have been termed "vitamins."

Without entering into a discussion as to their action, it is recognised that the infant needs at least five for normal growth. Probably the administration of the vitamins along with food-stuffs is insufficient; their absorption, too, is essential. Growth depends also upon the equilibrium of the internal secretions of the many glands and other tissues in the body. We have seen that excessive secretion of the cortex of the suprarenal or the anterior lobe of the pituitary gland is often associated with precocity and abnormal growth. In the same manner atrophy of these tissues may lead to lack of development, which has been termed "Infantilism"—a term far from satisfactory, since it is not an infantile but a puerile condition that results: the ratio of head, trunk and limbs is not that of an infant but rather of an individual before puberty. So far this condition has been found associated with morbid changes in the pituitary, suprarenal cortex and also thyroid, kidneys, pancreas and perhaps intestinal flora.

PITUITARY.—(1) Overgrowth due to hypertrophy, see Acromegaly, p. 476. (2) Retarded growth due to atrophy, see Dystrophia Adiposogenitalis, p. 478. (3) Infantilism.

INFANTILISM.—(a) *Brissaud type.*—This type presents—besides the ordinary attributes of infantilism—certain signs of partial thyroid insufficiency, not to be confounded with myxœdema resulting from total thyroid insufficiency. The principal characteristics of this infantilism are—smooth face, protruding eyes, thick lips, fat round cheeks, fine hair, poor eyebrows and eyelashes. large head compared with the body, stomach slightly prominent, infantile pelvis, thick limbs due to a fatty cushion which covers all the body and hides the muscles and bones, arrested development of the epiphyses, delayed

appearance of ossification, delay or absence of second teeth, absence of hair on the pubis and axillæ, rudimentary sexual organs, high voice, larynx little prominent, thyroid gland generally small, and childish mind.

(b) *Lorain type*.—This is perhaps due to a similar cause. This type presents the following characteristics: The body is small, but the limbs are no longer those of a child. There is no disproportion between the head (which is small) and the rest of the body. The facial features are well-modelled, the neck is long, the shoulders broad and the muscles (being rid of childish fatness) are well-formed. The stomach is not prominent. The pelvis is narrow, and the lower limbs long and well-formed. Generally the epiphyses are atrophied. The voice is pitched high. Finally, if they lack the hairiness of a male (for they have no hair on the face, and little on the pubis and axillæ) they have, however, well-formed sexual organs, not very large but well-proportioned to the rest of the body. In short, they are men in miniature, since their body has undergone the change from an infant to an adult.

SUPRARENAL CORTEX.—(1) *Hypertrophy*.—Precocity, see p. 456.

(2) *Atrophy*.—Probably progeria, i.e., retarded growth with early senilism. The characteristic features of the condition are—the absence of subcutaneous fat, which allows the muscles, cartilages, bones, veins and tendons to be outlined with remarkable clearness: the absence of hair except fine grey hair, on the scalp, eyebrows and eyelids: the skin is dry and thin, the nails short and flat, the stature is short, the milk teeth are retained, and the sex glands undeveloped. The senile peculiarities have been found at autopsy, too, the blood vessels being those of an old man—thickened and hard.

THYROID.—See Cretinism, p. 468.

RENAL DWARFISM.—Dwarfism, associated with bone deformities, has been described in interstitial nephritis beginning in early childhood. In seven cases recently collected, the average was 12 inches below the normal height for the age of the patient. Along with the lack of growth, changes in bone occur, which lead to genu valgum, and this is a fairly rapid development. In many ways the changes in the bones are similar to those of rickets. The onset of the disease is insidious, whilst the termination is from uræmia. Renal disease may or may not be associated with want of development of the sex glands.

PANCREATIC DWARFISM.—Retarded growth, associated with defective pancreatic secretion, has been described. In one case a youth of nearly 19 years old had suffered from chronic diarrhœa for 9 years, and had the appearance of a boy of 10, the voice being shrill and genitals undeveloped. The administration of pancreatic extract controlled the diarrhœa, he gained 23 lb. in weight and grew 5 inches in 3 years, whilst the voice changed to that of a man and the sex organs developed.

ARRESTED GROWTH OF UNKNOWN ORIGIN.—*Ateliosis*.—No satisfactory explanation has been offered to account for the lack of growth which results in the adult (normal in all respects) attaining only 24 inches in height. One must draw a very definite distinction between dwarfism and infantilism, for the dwarf may produce offspring which attain normal proportions. A certain number of dwarfs remain puerile. The "Lorain" type seems but slightly different.

POLYGLANDULAR SYNDROME

The interdependence of one tissue upon another makes it easy to understand how over or under activity of one internal secreting gland may lead to changes in other glands and tissues. It seems probable that when methods of investigation become more elaborate, polyglandular syndrome will be found to be much commoner than disease of only one of the internal secreting glands. Polyglandular syndrome will naturally depend upon which gland is primarily affected, and to what extent the other glands are involved. The cortex of the suprarenal appears to be easily affected, and among the cases of this syndrome excessive growth of hair, with slightly abnormal distribution, is quite common. The pituitary gland and the thyroid gland are linked fairly closely. It is generally accepted that in the condition called Decreaux's disease both of these glands are affected; but there is considerable difficulty in deciding whether the depression of the activity is primarily of the pituitary or of the thyroid. A knowledge of the main changes which follow over or under activity of the internal secreting glands is of help in deciding which glands are at fault in any specific case; nevertheless surprises at autopsies are not infrequent.

THE SEX GLANDS

THE TESTES

There is conclusive evidence that the testes supply an internal secretion in addition to the manufacture of spermatozoa. This evidence is based upon the changes which follow the removal of the testes in young animals and young human beings, and also from the experimental introduction of testicular tissue into female animals.

The testis consists of two essential types of cells: the interstitial cells of Leydig, and those forming the convoluted tubes. Spermatozoa arise from the latter. Some think that the internal secretion is derived from the interstitial cells alone, while others think that, in addition to germinating spermatozoa, the convoluted tubes produce an internal secretion as well. An academic question of considerable interest arises as to whether premature sexual development, along with secondary sexual characteristics, ever occurs from testicular hypertrophy, or whether the substance which causes the overgrowth of the testes also causes the other changes simultaneously. Precocious development of the testes is associated with hypertrophy of the suprarenal cortex, and sometimes with tumour of the pineal gland.

Insufficiency, atrophy, removal, or destruction of the testes before puberty leads to failure of development of male characteristics: the body becomes fat and large, the voice remains of high pitch, and the hair scanty. This suggests that the internal secretion of the testes is essential for the normal activity of other internal secreting glands, such as the pituitary, the suprarenal, and the thyroid; in other words, the katabolites of some cells appear to be

the anabolites of other cells, and no type of cell can lose its activity without other cells suffering.

Transplantation of testicular tissue has been performed with alleged success, but it is difficult to understand in what manner, since the testicular tissue is replaced by fibrous tissue in a comparatively short time. So far the preparation of an active principle for therapeutic use has eluded investigators.

THE OVARIES

It is not customary to include diseases of the ovary, which are numerous, in a text-book of medicine, but since changes in the internal secretion of that organ may have a profound effect upon general health, some reference, even if brief, seems advisable.

It is generally accepted that, even before puberty, the ovary itself produces an internal secretion; indeed, this seems proved conclusively by the effect of the removal of the gland in animals and in human beings: the subject loses many of the female characteristics, and may develop some of those of the male, and also fat. The mature ovary, in addition to the foregoing, produces an internal secretion which regulates menstruation, and is a factor in parturition.

O. LEYTON.

SECTION VIII

DISEASES OF THE DIGESTIVE SYSTEM

DISEASES OF THE MOUTH

ORAL SEPSIS ¹

ORAL sepsis is the condition in which excessive bacterial activity occurs in the mouth. Apart from actual infection in connection with the teeth and gums, it develops whenever insufficient attention is paid to the cleanliness of the mouth. Thus particles of food may stagnate between the teeth and under bridges and other fixed dental work, as well as in connection with plates which are not removed and washed with sufficient frequency. Dental fillings, caps and crowns, which have not been accurately fitted, may allow small accumulations of stagnant and decomposing matter, which are fertile sources of oral sepsis, to collect.

The mouth should be thoroughly examined in every patient, from whatever condition he may be suffering, but with special care in all digestive disorders, and in those conditions which will be presently described as possible sequels of oral sepsis, even if the patient says he has never suffered from toothache and that he regularly visits the dentist. The examination is most simply done with a small electric torch and a wooden spatula, which is burnt directly after use. In patients who wear tooth-plates, the mouth should be examined both before and after their removal. Each tooth and the gum surrounding it should be carefully inspected. The presence of tartar and red swollen gums indicates that some infection is present. In doubtful cases the patient should be sent to a dentist for an expert opinion, and if no obvious disease is found, radiograms should be taken, as they alone can show with certainty the existence of septic foci under apparently well-fitting crowns and fillings, and at the roots of teeth which are otherwise perfectly healthy, and they make it possible to determine with great accuracy the extent of any periodontal infection.

DENTAL HYGIENE

Neither dental decay nor dental sepsis occurs if the teeth are always kept free from food between meals. The teeth should, whenever possible, be thoroughly cleaned immediately after each meal, and no food should be taken between meals. If the teeth are brushed straight across, the food is removed from the outer surfaces but not from the spaces between the teeth. If they are brushed with a circular or up and down motion, the gums are

¹ I am indebted to Mr. A. L. Spencer-Payne for help in revising this section

injured and there is a tendency to push them away from the necks of the teeth. Where the gum is already inflamed and loose, as is often the case in pyorrhœa, the food will be brushed under the loose gum and the condition aggravated. The correct method is to sweep the brush in one direction only. On the outer or cheek surfaces the brush should be used with a twisting motion from the gums towards the teeth, i.e. downwards in the upper jaw and upwards in the lower jaw. When sweeping the inner or tongue surfaces of the teeth the brush is held perpendicularly, so that only the end comes into use; it is pulled downwards in the upper jaw and upwards in the lower jaw. Special care should be taken to reach the back and sides of the last molars or wisdom teeth. The neck of the tooth should be kept clean by wiping with small swabs of wool in curved dental tweezers.

The tooth brush should have a small head, a straight handle, the rows of bristles should be spaced, and the bristles on the tip should be shaped into a groove, so as to take the contour of the teeth when it is used perpendicularly for the inner surfaces.

Normally the gums completely fill the spaces between the teeth, but when they begin to recede, as in pyorrhœa, these spaces are no longer filled and food collects between the teeth. This food cannot be removed by a tooth-brush. The brushing must then be followed after each meal by the use of a tooth-pick, and preferably of metal, with a very fine blade bent at an angle so that it will pass readily between the molar teeth, followed by a strong spray, which will force water between the teeth and clear the spaces of food.

Patients with inflamed gums or pyorrhœa should also massage the gums with the forefinger and thumb from the gum towards the teeth after using the brush and before using the spray, and the dried gum margin should be painted with tincture of iodine once a day, using curved dental tweezers and a very small swab of wool for the purpose.

Artificial teeth should never be worn at night, but should be kept in antiseptic. In addition to this, they should be very thoroughly scrubbed with a brush and soap and water, so far as is possible after every meal.

Children should be given food which requires thorough mastication, as soft food, which can be swallowed without chewing and with the production of little or no saliva, is likely to cause stagnation of sticky carbohydrate material between the teeth.

At the end of each meal some fluid should be drunk, or some fresh fruit, the acid of which excites the flow of saliva, should be eaten in order to keep the teeth clean. The alkaline saliva neutralises the acid of the fruit and prevents it from damaging the teeth. Mouth-breathing in children should be corrected by direct treatment of nasal obstruction and by respiratory exercises. The teeth should be examined twice a year, even when there is no reason to suppose that anything is abnormal, so that tartar can be removed, early caries dealt with, and pyorrhœa alveolaris recognised and treated in its earliest stage.

(1) PYORRHOEA ALVEOLARIS ; CHRONIC PERIODONTITIS

Ætiology and Pathology.—Stagnation of food mixed with pyogenic organisms between the teeth leads to inflammation of the edge of the gums—marginal gingivitis. The toxins produced by the organisms destroy the

attachment of the muco-periosteum to the neck of the tooth, and a pocket develops between the tooth and the gum. The margin of the alveolar process is then slowly destroyed as a result of rarefying osteitis, until it may finally be replaced by granulation tissue. Stagnation of infective material in the pocket leads to gradual extension of the disease and aggravation of the gingivitis. Much pus is produced, the condition at this stage being commonly known as *pyorrhœa alveolaris*. In some cases, however, advanced destruction of the tooth socket occurs with little gingivitis or pus formation.

Symptoms.—In marginal gingivitis the edge of the gum of one or more teeth is red, swollen and bleeds with abnormal ease when brushed, the first part to be affected being usually the interdental papillæ. When *pyorrhœa alveolaris* has developed, pockets are present round the teeth, and pus can generally be seen exuding from the edge of the gum; even when none is seen on first examining the mouth, beads of pus appear if the edges of the gum are pressed. In chronic cases the teeth are often loose. Reflex salivation occurs, and an excessive quantity of mucus is secreted by the small mucous glands of the mouth. The accumulation of decomposing food, debris and pus in the pockets round the teeth produces an unpleasant taste in the mouth, most marked on waking in the morning, and this is also a common cause of foul breath. It is rare for any pain to develop, and the slight discomfort which may be present is generally insufficient to induce the patient to consult a dentist.

The inflamed condition of the gums often leads to a general stomatitis, and sometimes to chronic pharyngitis and tonsillitis. *Pyorrhœa alveolaris* does not by itself produce chronic superficial glossitis, but it predisposes to that condition in syphilitic patients, especially if they drink and smoke excessively. Periodontitis in the upper jaw may lead to infection of the maxillary antrum, and infection of any of the other nasal sinuses may occur. The danger of pulmonary complications following general anæsthesia is greatly increased if the mouth is in a septic condition.

Most of the pus which is constantly forming round the teeth is swallowed; the amount may be very considerable, as the ulcerated area round each tooth may be as great as half or even one square inch. During the day, the pus and bacteria are so diluted by what is eaten and drunk that they cannot do much damage, most of the bacteria being destroyed by the hydrochloric acid in the stomach. During the night, however, when no hydrochloric acid is secreted and nothing is eaten or drunk, the pus and organisms which are constantly swallowed with the saliva may infect the stomach and intestines. *Pyorrhœa alveolaris* is thus an important factor in the production of chronic gastritis, enteritis, colitis, appendicitis and gastric and duodenal ulcer, although one or more additional factors are necessary for the production of each of these diseases, as many people with *pyorrhœa alveolaris* suffer from no digestive disturbance. Duodenal catarrh, secondary to oral sepsis, is sometimes a cause of infection of the biliary passages and pancreas. When oral sepsis is associated with achlorhydria, it may be a factor in the development of Addison's (pernicious) anæmia and subacute combined degeneration of the spinal cord.

In some individuals the local reaction is sufficient to prevent the passage of toxins and organisms from the infected gums into the circulation. In many cases, however, toxins are absorbed. Areas of subinfection may also result

from the passage of bacteria into the circulation and thus further increase the toxæmia. General ill-health follows, and it may be accompanied by septic anæmia and chronic slight pyrexia. Predisposed individuals may develop rheumatoid arthritis, fibrositis, neuritis, and less frequently iridocyclitis, and even septicæmia and infective endocarditis. Other forms of joint disease, such as gout and osteo-arthritis, are often aggravated by the toxins resulting from oral sepsis. The development of gastric and duodenal ulcer, appendicitis and cholecystitis, as a sequel to oral sepsis is probably primarily due to toxæmia produced in this way, the ascending or surface infection for swallowed organisms being generally secondary. Various disorders of the skin, such as chronic eczema, urticaria, rosacea and erythema may also occur. The causal connection between these conditions and pyorrhœa alveolaris is shown by their temporary aggravation after injecting an overdose of autogenous vaccine and in some cases after extracting the teeth.

Treatment.—Local treatment by scaling, massage of the gums to expel débris from the pockets, and irrigation of the pockets with hydrogen peroxide often checks suppuration; but the pockets remain, and patients should be instructed in the care of their teeth or recurrences are certain to occur. Kataphoresis, vaccine treatment and eradication of the pockets by cutting away the gum, or treating the pockets with ammoniacal silver nitrate followed by formalin, are also of value, but a complete and permanent cure is almost impossible except in very early cases. Palliative treatment should be reserved for cases in which only local symptoms are present, but even then the teeth should be removed before too much destruction of the alveolar processes has taken place for comfortable dentures to be made, and also if the teeth are loose or the pockets very deep.

When pyorrhœa alveolaris has led to disease in other parts of the body than the mouth, palliative treatment is useless and dangerous. The teeth should be removed after thoroughly cleaning the pockets, but it is often wise to give a few doses of autogenous vaccine first in order to reduce the danger of an acute exacerbation of symptoms, which might otherwise result from the absorption of toxins from the large bare surfaces left after removal of the teeth.

Extraction should not be postponed because a patient is seriously ill; it is no more reasonable to wait until improvement occurs when the symptoms are due to septic teeth than to postpone an operation for acute appendicitis, and I have seen more than one death result from this unreasoning fear of extraction. A general anæsthetic should be given and all the diseased teeth should be removed at the same time. An exception, however, should be made in the case of such conditions as Addison's anæmia and rheumatoid arthritis, in which it is safer to remove two or three teeth at a time under a local anæsthetic to avoid the risk of a severe general reaction. Although the masticatory power of artificial teeth is only about one-fifth of that of normal teeth, indigestion is unlikely to result if care is taken to avoid tough meat and hard food. Even in the absence of artificial teeth no disturbance of digestion follows if only soft food is taken. The removal of the teeth does not invariably result in the complete eradication of the disease, as radiograms may still show small areas of rarefying osteitis, from which it may be possible to obtain cultures of streptococci, which continue to give rise to general symptoms. Scraping the diseased bone away, followed by the use of an autogenous

vaccine is the most satisfactory treatment for such residual foci of infection.

(2) DENTAL CARIES

Ætiology and Pathology.—Dental caries is caused by the action of organic acids produced by bacterial decomposition of stagnating carbohydrate food. Progressive destruction of the tooth substance occurs until the pulp cavity is exposed. Mouth-breathing is an important cause of caries in children, as it dries the mouth and tends to increase the decomposition of the food debris in contact with the teeth.

Symptoms.—Carious teeth are tender and their presence renders mastication painful. The patient therefore avoids using the affected teeth, and this favours the deposit of tartar and the stagnation of food. If many teeth are affected the food is bolted, so that indigestion is likely to occur owing to insufficient mastication, quite apart from the infection of the alimentary canal caused by swallowing septic material from the mouth. The irritation produced by the decomposition of stagnant food around the teeth gives rise to marginal gingivitis and pyorrhœa alveolaris. Oral sepsis produced in this way is of much more importance than that caused by the caries itself, as the quantity of decomposing material and bacteria swallowed from dental cavities is comparatively small, and no local absorption of toxins or bacteria can occur so long as the pulp cavity is not reached. When the latter becomes infected, absorption of poisons is likely to lead to enlargement of the cervical glands, especially in children, and the chronic inflammation produced in this way is a common precursor of tuberculous infection of the glands. Inflammation of the pulp spreads to the periodontal membrane and may finally produce an alveolar abscess.

Dental caries is the most common cause of toothache, and pain is often referred to various situations more or less remote from the teeth. In all cases of trigeminal neuralgia a thorough examination of the teeth should therefore be made.

Treatment.—Dental cavities produced by caries should be filled at the earliest possible moment, but if this cannot be efficiently done the teeth should be removed, as tender teeth which prevent proper mastication are a much greater source of danger than the absence of teeth, even in very young children. Removal of all the teeth in children may cause narrowing of the dental arch and consequent crowding of the permanent teeth, but this can be easily remedied by treatment, whereas the septic condition of the mouth caused by extensive caries may lead to permanent ill results.

(3) APICAL INFECTION

Ætiology.—Apical infection is infection of the apex of the root of a tooth. This can only occur if its pulp is dead, except in rare cases of extensive caries.

Symptoms.—Apical infection may be acute or chronic. In the former an alveolar abscess forms; this gives rise to the usual symptoms and signs of inflammation. Chronic apical infection, on the other hand, frequently gives rise to no pain or discomfort and no signs recognisable on ordinary examination. It can then only be recognised in a good radiogram.

Treatment.—In cases of only moderate severity the pulp canal should be opened and sterilised with ammoniacal silver nitrate followed by formalin, or the infected area beyond the root apex can be ionised through the pulp canal with iodine or zinc chloride. In more advanced cases, and in all in which serious secondary symptoms are present, extraction should be performed without delay and the socket should be curetted.

STOMATITIS

CATARRHAL STOMATITIS

Ætiology.—Catarrhal stomatitis is common in ill-nourished children during dentition, and in association with gastro-intestinal disturbances. In adults it may result from excessive consumption of alcohol or highly-seasoned food or excessive smoking. It is sometimes present in the specific fevers, and may also be caused by septic teeth.

Symptoms.—The gums and lips are often affected alone: in other cases the whole mouth, including the tongue, is involved. The mucous membrane is red and dry, but excess of mucus may be secreted by the small buccal glands. The tongue is swollen and furred.

The mouth is uncomfortable, and occasionally actual pain is present, especially on mastication. The general health is unaffected.

Treatment.—The teeth should be cleaned with special care, and the tongue kept as free as possible from fur by scraping. A mouth wash should be used after each meal, and borax and glycerine should then be applied to the inflamed parts.

THRUSH

Ætiology.—Thrush is most common in weak, emaciated infants with gastro-intestinal symptoms, who have been fed with an unsuitable diet, and whose mouths have not been kept clean. Acid fermentation of food remnants leads to catarrhal stomatitis, and this is likely to be followed by thrush. Thrush may occur in epidemic form in badly managed institutions, being spread by dirty feeding bottles. The disease may also occur in enfeebled adults in the late stages of tuberculosis, cancer and diabetes, and in severe febrile infections.

Pathology.—Thrush is caused by infection with *Oidium albicans*, a fungus, the filaments of which form a dense felt-work in the superficial epithelial layer of the mucous membrane.

Symptoms.—Thrush generally appears first on the tongue, and then on the cheeks, lips, hard palate, tonsils and pharynx. In rare cases the entire buccal mucous membrane is covered, and the infection may even spread to the vocal cords, œsophagus and stomach. It begins as slightly raised, pearl-white spots, which gradually grow and then coalesce. The white material can be readily detached, leaving either intact mucous membrane, or, in more severe cases, a bleeding and ulcerated surface.

Diagnosis.—Adherent milk curds may superficially simulate thrush. In aphthous stomatitis the white patches are at first vesicles and then definite ulcers, and salivation is present in contrast to the dry mouth in thrush. A definite diagnosis can only be made with the aid of the microscope.

Treatment.—Thrush should be prevented by keeping the mouth clean and babies' bottles sterilised. When once developed it is most important to improve the patient's general health as well as to give local treatment. The mouth should be washed with sodium sulphite solution (1 drm. to 1 oz.), after which the thrush can be easily scraped off.

ULCERATIVE STOMATITIS

(a) APHTHOUS (OR VESICULAR) STOMATITIS.

Ætiology.—Apthous stomatitis occurs especially in children under 3, either alone or associated with some febrile or digestive disorder.

Symptoms.—The apthæ consist of small slightly raised vesicles, each surrounded by a red areola. Within 24 hours the vesicles rupture, leaving grey ulcers, 2 to 4 mm. in diameter, with bright red margins. The ulcers heal rapidly. They occur especially on the inner surface of the lips, the edges of the tongue, and the inside of the cheek; in severe cases the pillars of the fauces may be affected.

The mouth feels sore, and the child is unwilling to take food. Salivation is frequently present.

Treatment.—The mouth must be carefully cleaned after meals and washed with potassium chlorate solution (grs. x ad 5i). Borax and glycerine should then be applied. In severe cases the ulcers may be treated with silver nitrate.

(b) FOLLICULAR STOMATITIS.

Ætiology.—Follicular stomatitis may occur at any age, but especially in nursing women.

Symptoms.—The mucous follicles of the lips and cheeks become inflamed and swollen; the epithelium over them breaks down, and ulcers, 3 to 5 mm. in diameter, result. They may cause no trouble, but more commonly they give rise to a considerable amount of pain on taking food, and to reflex salivation.

Treatment.—The ulcers heal rapidly after being touched with silver nitrate.

(c) MERCURIAL STOMATITIS.

Ætiology.—Stomatitis may occur when large doses of mercury are taken, especially in individuals already suffering from oral sepsis. Some people are especially susceptible to mercurial poisoning, and develop stomatitis after taking a comparatively small quantity.

Symptoms.—The gums become sore, red, swollen and finally ulcerated; mastication is painful. Salivation occurs, and the salivary glands may be enlarged, tender and painful. The tongue is swollen, and the neighbouring lymphatic glands are often enlarged. The breath is foul, and the patient complains of a metallic taste. Formerly, when mercury was given with less care than at present, the teeth often became loose, and the pharynx affected; but these complications are now rare.

Treatment.—The administration of mercury should at once be discontinued. The bowels should be well opened by giving salts in order to facilitate the elimination of the mercury present in the body. Potassium chlorate (grs. x) should be taken three times a day; it has the advantage of being re-excreted into the mouth by the salivary glands.

(d) ULCERO-MEMBRANOUS STOMATITIS.

Ætiology and Pathology.—Severe ulcero-membranous stomatitis occurred in epidemic form among the troops in England and France during the war. It is comparatively rare in civilians. It appears to be caused by infection with the same spirilla and fusiform bacilli which Vincent found in the form of pharyngitis known as Vincent's angina.

Symptoms.—All parts of the mouth and pharynx may be involved, but the margins of the gums are specially liable to be affected. The gingivitis which results is generally more severe than that caused by pyorrhœa alveolaris, and pockets of pus do not develop. The stomatitis is similar to that caused by mercury, and the gums may be so swollen and bleed so readily that scurvy is simulated. The breath is fœtid, and the gums may be sufficiently tender to make mastication painful.

The disease generally runs a chronic course, but is sometimes acute. It generally does not give rise to any severe constitutional disturbance, but may occasionally do so.

Treatment.—The stomatitis rapidly disappears with treatment by injection of neo-salvarsan or allied arsenical preparations.

GANGRENOUS STOMATITIS

Synonyms.—Cancrum Oris; Noma.

Ætiology.—This rare disease occurs in children, especially girls, and especially between the ages of 2 and 5; it is rare except under very insanitary conditions. It generally develops during convalescence from an acute fever, especially measles, and less frequently scarlet and typhoid fever. No specific organism has been found.

Symptoms.—A sloughing ulcer develops on the inside of the cheek or on the gums; it rapidly spreads and leads to brawny induration of the skin of the cheek. Occasionally it heals spontaneously, but more frequently it perforates the cheek or spreads to the tongue, chin, jawbone or eyelid and eye.

Cancrum oris is accompanied by severe constitutional symptoms, the patient being prostrated with a high temperature and rapid pulse; diarrhœa or broncho pneumonia frequently follows, and death generally occurs between 7 and 10 days of the onset.

Treatment.—The only adequate treatment is to destroy the diseased part as completely as possible with the cautery.

DISEASES OF THE SALIVARY GLANDS

FUNCTIONAL DISORDERS

PTYALISM

Definition.—Excessive secretion of saliva.

Ætiology.—The flow of saliva is increased by reflexes originating in the mouth and also in more distant situations. Thus all pathological conditions in the mouth and its neighbourhood, such as stomatitis, cancer of

the tongue and carious teeth, especially if associated with pain, are accompanied by salivation. The irritation of the mouth caused by excessive smoking gives rise to ptyalism. Trigeminal neuralgia, whatever its cause, is frequently associated with a reflex flow of saliva. Mechanical irritation of the œsophagus causes a secretion of saliva; this is well seen in the salivation which results from the passage of a tube into the stomach, and when a large bolus of food or a foreign body becomes lodged in any part of the œsophagus. The same reflex is the cause of the salivation, which is a common symptom in achalasia of the cardia and in cancer of the œsophagus.

When the acidity of the gastric contents is abnormally high, an impulse is conveyed by the vagus to the salivary centre in the medulla, and reflex salivation results; consequently ptyalism occurs at the height of digestion in many cases of duodenal ulcer.

The salivation which may occur during menstruation and in early months of pregnancy is also probably reflex in origin.

Salivation due to any of the causes already described may be exaggerated or perpetuated by auto-suggestion. This hysterical ptyalism is often complicated by a spitting or swallowing tic; the latter is always accompanied by aerophagy, so that flatulence is produced.

Ptyalism is also caused by the specific stimulating action of certain drugs, such as pilocarpine, and also by drugs, such as the iodides and mercury, which are partially excreted by the salivary glands, the cells of which they irritate.

Symptoms.—Excessive salivation may interfere with digestion, by diluting the gastric juice, the acid of which is also to some extent neutralised by the sodium bicarbonate it contains. Every time saliva is swallowed some air passes with it into the stomach, which may therefore become distended with swallowed air. For this reason ptyalism is a common cause of aerophagy. It may also cause waterbrash (see p. 510).

Treatment.—In order to cure ptyalism the primary cause must be discovered and removed. As purely symptomatic treatment belladonna should be given; 5 minims of the tincture taken three times a day half an hour before meals is sufficient in the majority of cases, but occasionally larger doses are required. The drug has the additional advantage of diminishing the secretion of gastric juice when gastric hypersecretion is the primary cause; in such cases oxide of magnesia taken after meals also diminishes the flow of saliva, by neutralising the excess of acid in the stomach. Hysterical ptyalism can be cured by psychotherapy.

XEROSTOMIA

Ætiology.—The dry mouth, which is constantly present in fevers, especially typhoid fever, is due mainly to deficiency in the psychological, chemical and mechanical stimuli to salivary secretion. It is probable that the toxins of the diseases also exert some direct inhibitory action on the gland-cells. Depressing emotions, and loss or perversion of taste, which may occur when the tongue is furred, result in diminution in the psychological secretion, and atropine paralyses the secretory nerve-endings. The secretion of saliva is also diminished when excessive quantities of fluid are lost by other channels, as in diabetes and severe diarrhœa. Diseases of the salivary glands them-

selves, such as mumps, result in diminished secretion. Severe xerostomia occasionally develops without any obvious cause. Xerostomia is also a common result of sleeping with the mouth open ; in this case there is of course no deficiency in the salivary secretion.

Symptoms.—Deficient secretion of saliva causes the mouth to become dry and septic, as particles of food remain between the teeth, where they undergo bacterial decomposition. The tongue is furred and there is often an unpleasant taste in the mouth. It is difficult to chew the food sufficiently, and the appetite is impaired as a result of the condition of the mouth and the difficulty in tasting the food. The insufficiently chewed food is likely to irritate the stomach. In severe cases, dysphagia occurs and speech becomes difficult. The absence of digestion of starch is of no great importance, owing to the amylolytic functions of the pancreatic and intestinal juices.

Treatment.—A diet should be chosen which stimulates the flow of saliva as much as possible ; acids are most active, then salt and bitter substances, whilst sweet substances have very little action. The food should be given in as appetising a form as possible, and masticated very thoroughly. If the saliva is only slightly deficient, dry biscuits should be taken at each meal. The taste of a bitter mixture taken immediately before meals may directly stimulate the flow of saliva, and pilocarpine should also be tried, but it is rarely of much use, unless a sufficiently large dose is given to cause unpleasant symptoms, such as sweating. Great care should be taken to keep the teeth clean, and the mouth should be washed after each meal.

ORGANIC DISORDERS

SPECIFIC PAROTITIS : MUMPS (see p. 287)

PAROTITIS

Ætiology.—Acute parotitis is almost always due to infection ascending Stenson's ducts from the mouth, when the latter has become septic owing to the absence of chewing and normal salivation in patients who have been taking a fluid diet during a febrile illness, especially typhoid fever and cholera, or who have been starved on account of oesophageal obstruction, or in the treatment of gastric ulcer. Now that the importance of keeping the mouth clean in illnesses of every kind has become more widely recognised, and prolonged starvation is very rarely used in the treatment of gastric ulcer, acute parotitis has become comparatively rare. I have seen several attacks of subacute parotitis occur in the course of four years in a young woman with tuberculous mesenteric glands, and a similar condition has been described in Hodgkin's disease. It may also occur as a complication of salivary calculi.

Symptoms.—Both parotid glands are generally affected, except in mild cases when the condition is often unilateral. The glands are enlarged and tender. The skin is stretched and shiny. In slight cases the inflammation gradually subsides ; in severe cases suppuration takes place, the skin over the glands becomes oedematous, the neighbouring lymphatic glands are enlarged, the temperature is high, and severe constitutional symptoms are present. The mouth is dry and very difficult to keep clean ; the tongue is covered with

a thick, dry fur. The mouth of Stenson's duct is everted and forms a small red nodule, from which a bead of turbid fluid or actual pus can sometimes be squeezed. In rare instances the non-suppurative form of acute parotitis becomes chronic. The parotid glands are permanently enlarged and secrete no saliva. I have also seen a similar chronic parotitis follow a subacute attack, for which no explanation beyond a mild degree of oral sepsis could be found.

Treatment.—The mouth should be kept clean with the greatest care. Pain is relieved by the application of an ice-bag, and the flow of saliva should be promoted by means of chewing-gum. If suppuration occurs the glands must be incised.

ARTHUR F. HURST.

DISEASES OF THE TONSILS

ACUTE TONSILLITIS

Tonsillitis has been classified as superficial, follicular or lacunar, and parenchymatous, according to the degree in which the various parts of the gland bear the brunt of the inflammation; the distinction, however, is not a definite one, as the entire organ is necessarily inflamed.

Ætiology.—The disease is rare in children below the age of 5 or 6, and after middle age; and it is commonest in spring and autumn. It is predisposed to by general ill-health, overwork and a polluted atmosphere; the escape of sewer-gas from defective drains is undoubtedly a cause, and the infection may be carried by water or milk. It occurs as a regular symptom of scarlet fever, measles and diphtheria. There is a very close connection between rheumatism and tonsillitis, and it was formerly believed that tonsillitis was of rheumatic origin; but it is now generally recognised that both acute rheumatic fever and chronic rheumatic pains in joints and muscles are frequently caused by septic infection through the tonsils. Unhealthy conditions of the tonsils due to previous inflammation strongly predispose to further attacks by causing adhesions in the crypts or supratonsillar fossæ, and between the tonsils and the pillars and plicæ, thus promoting the retention of secretion; previous partial removal acts in the same way.

Symptoms.—The symptoms are those of a feverish attack, together with a sore throat; the former often appear before the latter, and only examination of the throat reveals the cause of the disturbance. The temperature may rise to 103° or 105° F., and there is a variable degree of malaise, backache, headache and pain in the limbs. The soreness of the throat radiates to the ear, and is increased by attempts to swallow; the voice becomes thick, the breath foul, and the submaxillary and upper cervical glands are tender and swollen.

The tonsils are swollen, and their purple-red colour extends to the pharynx, palate and uvula—the latter frequently being œdematous. The surface of the tonsils is usually spotted over with yellowish masses of secretion which have exuded from the crypts; sometimes this secretion becomes confluent on the tonsils and occasionally, though rarely, it spreads beyond their surface—it is soft and readily wiped away. The tongue is coated, and the fauces covered with tenacious mucus. There is usually constipation, and

the urine is scanty and high-coloured, but not ordinarily albuminous. Albuminuria is, however, an occasional complication, as are pericarditis, endocarditis and suppurative otitis media.

Diagnosis.—The diagnosis from diphtheria is important, and sometimes difficult. The latter is more gradual and asthenic in onset, with less pain, less fever and a more rapid pulse, and the urine frequently contains albumin. The membrane of diphtheria is greyish-white rather than yellowish, and frequently spreads to the pillars and soft palate; whereas the exudation of tonsillitis rarely spreads, and never to any great extent, beyond the surface of the tonsils. The diphtheritic membrane is adherent and, when detached, leaves a raw bleeding surface, while that of tonsillitis is readily removed and more often discrete. In cases of doubt a bacteriological examination should always be made, and an injection of antitoxin should be given while waiting for the result.

Treatment.—The patient should be kept in bed in a warm well-ventilated room, an initial dose of calomel, 2 to 4 grains, should be administered and followed by a saline aperient. Externally, warmth is usually more comforting than cold, and a hot fomentation applied to the neck and covered by a large pad of cotton-wool gives some relief. Internally, especially if the fauces are clogged with tenacious mucus, a warm alkaline lotion, such as Dobell's solution, may be used with advantage, either by means of a spray or a rubber ball-syringe; but, if the inflammation is so severe that the patient is unable to open the mouth without pain, the lotion should only be used as a mouth-wash; gargling is, of course, only possible in very mild cases. Lozenges containing chlorate of potash, guaiacum or formalin may be employed. Of internal medication, sodium salicylate holds the favourite place in doses of 15 grains every 3 hours, and later three times a day; or aspirin, 10 grains, may be used instead; potassium chlorate in 15-grain doses, three or four times daily, appears to be helpful, especially in the follicular variety; and guaiacum, in the form of mistura guaiaci, was at one time in high repute. The patient must be encouraged to absorb as much nourishment as his dysphagia permits, and he will usually find that soft semi-solids are easier to swallow than liquids; there is room for ingenuity and resource in the provision of a suitable diet, such as junket, baked custard, ice-cream, meat jellies and soups thickened with corn-flour or arrowroot. An iron and quinine mixture may be given when the acute symptoms have subsided.

PERITONSILLAR ABSCESS OR QUINSY

Ætiology.—This is an acute affection due to the formation of an abscess outside the tonsil caused by septic secretions in the supratonsillar fossa or in the depths of a crypt bursting through the thin capsule of the tonsil into the surrounding loose areolar tissue. This process is favoured by adhesions obstructing the mouth of the supratonsillar fossa or the crypts, and, therefore, previous tonsillitis and imperfect surgical removal are predisposing causes. The abscess is usually situated above and external to the tonsil, but in rare cases is behind it.

Symptoms.—The affection is unilateral; but sometimes the opposite side is attacked, as the first recovers. It begins with a feeling of malaise,

fever, often a rigor, and severe pain radiating from one side of the throat up to the ear and into the neck; the cervical glands are enlarged and tender, and the neck stiff. Dysphagia is intense, the tongue thickly coated, and the breath foul. The mouth cannot be opened widely, and a good light is required for examination, when the typical large deep-red swelling is to be seen bulging one side of the soft palate. Pus forms in 2 to 4 days and, if left alone, will eventually burst, usually through the soft palate; relief is then immediate, but occasionally the opening closes prematurely and the abscess refills.

Complications.—Although one of the most painful and distressing of acute diseases, complications are uncommon, and death is very rare; it has occurred from rupture of the abscess, and inspiration of the pus, during sleep. Severe hæmorrhage may take place after spontaneous or surgical evacuation of the abscess when, as the blood may come from the internal carotid or from a branch of the external carotid artery, ligature of the common carotid is called for. The swelling has been known to spread to the larynx, and to necessitate tracheotomy. Suppuration of the cervical glands is a rare complication; pneumonia, septicæmia and pyæmia are also uncommon.

Treatment.—The general treatment is the same as that of severe acute tonsillitis, and the pain often calls for an occasional injection of morphine. Pus is probably present as soon as the swelling has assumed a well-defined rounded form, still more so if there is a boggy area in the centre. The abscess should be opened without delay, for this cuts short the attack and diminishes the risk of complications; but it does not always give immediate complete relief when there is marked cellulitis of the surrounding tissues. After the application of cocaine, a narrow sharp-pointed knife is introduced with the cutting edge upwards and the blade held in the sagittal plane; it is made to puncture the swelling at its most prominent part, and to enlarge the incision by cutting upwards as it is withdrawn. The knife should not be passed to a depth exceeding about $\frac{3}{4}$ inch; if pus is not struck, a sinus-forceps is introduced into the wound and pushed backwards until the pus is found, when it is opened widely to assist the evacuation. After the disease has subsided, removal of the tonsil is advisable, in order to prevent recurrence; it will usually be found that the gland has become adherent and requires dissection to ablate it completely.

CHRONIC TONSILLITIS

Chronic inflammation of the tonsils may, from the clinical point of view, be divided into two groups: Chronic Parenchymatous Tonsillitis or "enlarged tonsils," and Chronic Follicular Tonsillitis.

CHRONIC PARENCHYMATOUS TONSILLITIS

Enlarged tonsils in children are nearly always associated with adenoids; but adenoids are often found in children whose tonsils are not enlarged.

Ætiology.—This is similar to that of adenoids. The condition occurs chiefly in children between the ages of 5 and 15; but it frequently persists into adult life, although normal healthy tonsils atrophy about puberty and hypertrophy does not take place *de novo* after that age. The affection may

be the result of repeated colds or a sequela of scarlet fever, diphtheria, measles or whooping-cough.

Symptoms.—The symptoms are not easy to separate from those caused by the concomitant adenoids, if the latter be present; but it is certain that chronic inflammation of the tonsils can affect the ears, and that gastrointestinal disturbances and appendicitis are produced by the septic secretion squeezed out of the tonsils during deglutition. Recurrent attacks of follicular tonsillitis are common; and the cervical glands are frequently enlarged, may break down and suppurate, or may become tuberculous.

The objective appearances are very various, and it is extremely difficult to estimate the size, or even the healthiness, of a tonsil by inspection. Slightly enlarged tonsils may be prominent and may readily meet on gagging, while big tonsils are often largely buried in the palate or hidden beneath the plica triangularis—in which case a bulging can be seen at the side of the soft palate corresponding to the site of the upper pole.

Treatment.—For children with slight degrees of tonsillar hypertrophy palliative measures may be tried; an open-air, country life, preferably at the seaside, with cod-liver oil, malt, or iodide of iron, and a nasal lotion for the accompanying adenoids; paints are of doubtful utility, Mandl's solution (iodine, grs. vj, potassium iodide, grs. xij, peppermint oil, ℥ iij, glycerine, ʒi) is perhaps the best.

The tonsils should be removed when there have been repeated attacks of tonsillitis, after a quinsy, with any affection of the middle ear, when there is chronic enlargement of the cervical glands, and when rheumatic fever or chorea has occurred. It is usual now to remove the tonsils, if at all enlarged, when adenoid hypertrophy calls for operation in young children, because it is so often found that they subsequently increase in size and necessitate a second operation. When chronic cervical adenitis is present, and is not due to some other obvious cause, such as pediculosis or dental caries, the tonsils should be removed whether they appear diseased or not; in these cases about one-third of the tonsils are tuberculous, and this latent tuberculosis cannot be recognised by inspection. many of these tonsils, indeed, being quite small.

The reader is referred to surgical works for details of the operation, but it may be said here that, if a tonsil requires removal, it must be removed completely in its capsule, for the deeper portion of a diseased tonsil is quite as unhealthy as the superficial; trouble in the remaining portion is very common, and the previous operation only adds to the surgeon's difficulties. Nevertheless, the greater number of tonsils, and in children an overwhelming majority, can be quickly and certainly removed entire with the guillotine; removal by dissection is a far more formidable operation, and should be reserved for those tonsils which are adherent as a result of repeated inflammation, past quinsy, or previous incomplete operation.

CHRONIC FOLLICULAR TONSILLITIS

In older subjects, when fibrosis has followed the hypertrophy, the stenosed crypts become filled with yellowish-white caseous masses. The patient complains of an offensive taste, foul breath, often of recurrent attacks of sore throat, and of gastric disturbances. Not infrequently various forms of chronic

toxæmia, such as fibrositis or osteo-arthritis, are induced by absorption from these septic foci. In many cases the tonsils are quite small; they may look healthy, but pus can be squeezed out of the crypts on applying pressure at the anterior pillar by means of a flat instrument.

Treatment.—The treatment in the more marked cases is removal, and here dissection is often necessary. There are, however, a good many patients who have only a few unhealthy crypts in the tonsils; these may often be cured by passing a fine galvano-cautery point down to the fundus, several applications being usually necessary. The patient may also be shown how to clean out the secretion with a cotton-wool mop on a fine wooden applicator, and to paint the inside of the crypt with Mandl's solution.

VINCENT'S ANGINA

Ætiology.—This affection is believed to be due to two organisms, the bacillus and spirillum of Vincent growing in symbiosis; these organisms may be found in many ulcerative conditions of the mouth and throat, but their constant presence in this affection points to their specific character. The invasion of the throat is secondary to periodontal infection of the gums. It occurs especially in debilitated persons and under insanitary conditions and, though rare in civil life, was rather common during the Great War in some camps and barracks.

Symptoms.—The attack begins insidiously, with malaise, general pains and a temperature of 100° to 101° F. The pain in the throat is slight, but the glands on the affected side become enlarged and tender, and the breath is usually offensive. The affection is nearly always unilateral.

At first there is a patch of soft, yellowish detachable membrane on the affected tonsil which, in a day or two, comes partially away, exposing an ulcer with a well-defined margin. By the end of a week the membrane ceases to form, and the ulcer begins to heal. The ulceration may be quite deep in severe cases, but is ordinarily limited to the tonsil, and very seldom spreads to any distance from it.

Complications are very rare.

Diagnosis.—The disease is particularly interesting by reason of its liability to imitate diphtheria in its early stage, and syphilitic ulceration later. In both cases the discovery of numerous spirilla and fusiform bacilli in smear-preparations—they are difficult to cultivate—will help the physician to the correct diagnosis; but these organisms may also be found in tertiary ulceration, and the Wassermann reaction is occasionally positive in Vincent's angina. The subacute onset, the raised temperature and the tenderness of the glands aid the differentiation from syphilis; and from diphtheria, the milder constitutional symptoms, the extremely localised lesion, the soft friable character of the membrane and the absence of the Klebs-Loeffler bacillus.

Prognosis.—Death hardly ever occurs.

Treatment.—As the condition ordinarily clears up in a few days, it is difficult to estimate the effects of treatment. The usual remedy is the topical application of tincture of iodine after cleaning with peroxide of hydrogen. *Liquor arsenicalis* has been recommended as a mouth-wash, but it is poisonous if swallowed; it is better to apply it on a swab. Good results have been

reported from the local application of a solution of *salvarsan*, which may also be administered intravenously. Attention must be paid to the treatment of the gums and teeth.

HAROLD S. BARWELL.

DISEASES OF THE PHARYNX

DIVERTICULA (see p. 511)

ACUTE CATARRHAL PHARYNGITIS

This is not a very well-defined affection, and is usually accompanied by acute rhinitis on the one hand, and by laryngitis on the other; the tonsils also often participate in the inflammation.

Ætiology.—The affection is generally due to catching cold; it is also caused by traumatism of any kind and by the irritation of hot fluids, corrosives or chemical vapours, and it forms a part of various acute infectious fevers, such as measles, German measles, scarlet fever, influenza and typhoid.

Symptoms.—The discomfort varies from a tickling sensation, or the feeling of a lump in the throat, to severe dysphagia. The voice is husky and thick, and the cervical glands tender and somewhat enlarged. There is slight fever and general malaise.

The pharynx is to a varying degree red and swollen, especially at the sides behind the posterior faucial pillars, where the swelling forms the so-called "lateral bands." The palate is swollen and relaxed, and the uvula elongated. The posterior wall is often covered by a film of tenacious mucus.

Treatment.—The patient should stay in a warm room and avoid the irritation of smoking, talking, alcohol or irritating foods. Calomel, 2 to 4 grains should be given, and followed by a saline aperient. Aspirin, or sodium salicylate, is helpful, and, as the naso-pharynx is involved, the nose should be syringed with a warm saline lotion which may also be applied to the pharynx as a spray.

ACUTE SEPTIC PHARYNGITIS

By this term is implied a series of severe infective inflammations of the throat, including erysipelas of the throat, oedematous, phlegmonous and gangrenous pharyngitis and laryngitis, and angina Ludovici. Any classification must necessarily be a clinical one, based on the severity of the symptoms and their localisation, for they can be produced by a variety of micro-organisms, though they are usually caused by the *Streptococcus pyogenes*. These severe inflammations are fortunately uncommon, and most often, though by no means invariably, occur in debilitated or alcoholic persons.

Symptoms.—These vary greatly with the severity of the infection, which ranges from a mild inflammation to the most severe septic intoxication. They include malaise, sore throat, dysphagia, hoarseness and dyspnoea. The temperature in some cases rises to 105° or 106° F.; but in many of the worst cases it is hardly raised at all, and may be subnormal. Pleurisy, pneumonia and pericarditis may ensue, or death may result from asphyxia; but the

worst cases die from general toxæmia and heart failure, even within 24 hours of the onset of the disease.

The objective appearances, also, are very variable. The pharynx and palate are of a deep purplish-red, and there may be sloughy patches or pseudo-membrane. The entire mucosa may be enormously swollen, and the œdema may involve the upper aperture of the larynx and produce asphyxia. The sublingual region is sometimes occupied by a peculiar brawny swelling, of a hardness like wood, which spreads downwards into the neck to a variable extent, and is known as "angina Ludovici."

Treatment.—The patient must be in bed and well nursed, and every care must be used to ensure that he takes as much nourishment as possible. Poly-valent anti-streptococcic serum is sometimes very successful, and should be given early in a large dose (40 to 50 c.c.). Hot fomentations to the neck and inhalations of steam are comforting. Œdema of the upper aperture of the larynx should be treated promptly by scarification; free incisions should be made with a curved bistoury guided by the finger, and tracheotomy under local anæsthesia must not be delayed, if dyspnœa be severe or not relieved by scarification. For angina Ludovici a deep incision should be made, in the middle line, as all anatomical landmarks have disappeared, and an attempt should be made to find pus with the finger or a director.

RETRO-PHARYNGEAL ABSCESS

There are two forms—(1) Acute, and (2) chronic.

1. The acute form is a rare affection. It occurs in children up to the age of 3 or 4, but is far more frequently met with in the first 12 months. It is due to suppuration in the prevertebral glands, situated behind the posterior pharyngeal wall, which retrogress and disappear in life later. The abscess results from absorption of sepsis from the nares, naso-pharynx, or fauces, and is sometimes secondary to an infectious fever.

Though rare, the condition is an important one, for it may easily remain unrecognised in a young infant, and it is usually fatal if left unopened. The symptoms are fever and restlessness, a hoarse cry and croupy cough, with difficulty in swallowing and dyspnœa. Such symptoms should arouse a suspicion of retro-pharyngeal abscess, which may be seen on inspection as a rounded swelling of the posterior pharyngeal wall. The abscess is often very large, and must be freely opened in such a way as to avoid aspiration of the pus, without an anæsthetic, and with the child firmly held, either on the side with the face directed somewhat downwards, or on the back with the head hanging almost vertically. Recovery is rapid, and no after-treatment is required beyond attention to the enfeebled general health.

2. The chronic form, also, is found most frequently in children, but generally after the third year. It is of tuberculous origin, and is due either to tuberculosis of the prevertebral glands, or to caries of the cervical spine. The latter should be carefully excluded, for this abscess should on no account be opened through the mouth, as septic infection of the diseased bone will occur. The chronic glandular abscess, however, may be successfully opened and curetted by this route, though some surgeons prefer to treat them all by an incision behind the sterno-mastoid.

CHRONIC PHARYNGITIS

The symptoms of discomfort in the throat in the conditions grouped as chronic pharyngitis bear little relationship to the intensity of the changes seen on examination. Many people, especially heavy smokers, complain of no discomfort, in spite of showing decided chronic inflammation; whereas others, in particular dyspeptic or anæmic women or those at the menopause, suffer great discomfort, with no apparent local abnormality. Indeed, in many cases the condition is better described as pharyngeal hyperæsthesia.

Ætiology.—The causes of chronic pharyngitis are most often found in nasal disease, which produces inflammation of the pharynx by causing mouth-breathing, and by the irritation of discharges; incorrect production of the voice is an important factor which is often in its turn dependent on nasal obstruction. Unhealthy conditions of the teeth or tonsils are further causes, as are the inhalation of irritating dust and vapours in various occupations, tobacco smoke, and over-indulgence in alcohol. A long list of constitutional affections are active in the ætiology, such as gout, rheumatism, dyspepsia, anæmia, cardiac disease, cirrhosis of the liver, chronic bronchitis and pulmonary phthisis.

Symptoms.—The discomfort may take the form of aching, fullness, or feeling of a lump, a hair, or a pricking. The voice has a dead tone, and there is usually much hawking and frequent swallowings. The sufferer often becomes depressed, and fears that he has cancer of the throat. The unpleasant sensations are markedly lessened after a meal.

The mucosa of the pharynx and palate is thickened, and there is a loss of the finer modelling of the faucial pillars; the uvula is elongated, often slightly oedematous at its edges and tip, and fails to retract on phonation. The posterior wall is covered by a film of mucus, which puckers up and becomes more obvious on touching it with a probe or swab. The wall of the pharynx is traversed by enlarged venules, and sometimes it is set with slightly raised pink lenticular nodules of lymphoid tissue, constituting the well-known *granular pharyngitis*. In other cases two elongated masses of lymphoid tissue appear behind and parallel to the posterior pillars; these are the "lateral bands," and this form is called *lateral pharyngitis*. *Pharyngitis sicca* is a dry glazed condition usually dependent on rhinitis sicca or atrophic rhinitis, and occasionally the crust formation of the latter disease extends to the pharynx, causing a genuine *atrophic pharyngitis*.

Treatment.—The most important part of the treatment consists in the detection and alleviation of the cause, and should begin with a careful examination of the nasal passages. Cases of pharyngeal hyperæsthesia without obvious local changes are often harmed, rather than helped, by local treatment which directs attention to their trouble. Tobacco should be given up, and alcohol in concentrated forms, indeed the latter should be abandoned completely in plethoric patients and where the pharynx is congested; this type of patient is benefited by a morning dose of sulphate of soda or magnesia, a teaspoonful in a glass of hot water while dressing, or by one of the natural mineral waters. When the pharynx is dry, or covered with tenacious mucus, an expectorant mixture gives relief, such as, vinum ipecacuanhæ, ℥ xij, vinum antimoniale, ℥ v, iodide of potash, grs. iij, syrup of tolu, ʒi, water,

3i, three times a day. The throat may be sprayed with a hot alkaline saline lotion, and the same may be, with greater advantage, syringed through the nostrils. Of local applications in the form of paints, iodine is the most generally useful, and may be applied daily by the patient as Mandl's solution: iodine, grs. vi, potassium iodide, grs. xij, peppermint oil, ℥ ii, glycerine, 3i; a 5 to 10 per cent. solution of resorcin in glycerine may be employed, or, if a more astringent effect is desired, iron-alum 3i, in glycerine, 3i; or the physician may himself apply, once or twice a week, nitrate of silver, grs. x to xxx to the ounce of water. In many cases, the galvano-cautery is of great value; it acts as a counter-irritant and astringent, and should be applied lightly and with caution. Prominent granulations may be destroyed and enlarged venules obliterated by this means, but deep eschars should not be produced, and only a few applications should be made at one sitting.

KERATOSIS PHARYNGIS

In this condition a number of sharply defined projecting white or yellow nodules occupy the surface of the tonsils; they also occur, though less profusely, scattered over the lingual and naso-pharyngeal tonsils and on any lymphoid granules in the pharynx. They occur at any age after childhood, and usually in persons in a poor state of health. The causation is unknown; the nodules consist of heaped-up epithelium and detritus containing numerous micro-organisms of the kind ordinarily present in the mouth. They sometimes disappear quickly, in other cases they remain for many months, or they may frequently recur. They produce no symptoms, or at most a slight discomfort, and are of interest chiefly because they are frequently mistaken for the exudation of chronic follicular tonsillitis. Once seen they can, however, be recognised at a glance, for they are hard and adherent, discrete and prominent, and occur beyond the limits of the tonsils, on the pharynx and base of the tongue. They are usually discovered accidentally by the patient, who is naturally alarmed at their appearance. They are quite harmless, and local treatment is useless, for they are removed with difficulty and usually recur; it is wise to reassure the patient by telling him these facts and, if any treatment be required, to trust to attention to the general health, a holiday and change of air.

SYPHILIS

The primary chancre occurs on the fauces, occasionally on the pillars, palate or pharyngeal wall, but usually on the tonsil. In this situation the disease is apt to pass unrecognised, for the symptoms are usually slight and the lesion masked by the general inflammation of the tonsil; the typical induration is often absent, but there is always a characteristic bubo behind the angle of the jaw.

SECONDARY SYPHILIS

Secondary manifestations in the fauces are a part of the normal course of the general disease and are intensely contagious.

Symptoms.—The subjective disturbances are usually limited to dryness and discomfort. Objectively there are two types of lesion, erythema and mucous plaque. The former is a patchy, dusky red rash, with well-defined margins, somewhat symmetrical, and affecting especially the anterior pillars and soft palate. It is particularly associated with the early secondary symptoms; whereas the mucous patch may be present at the same time or may be found later, together with tertiary manifestations. The mucous plaque occurs on the soft palate, tonsils and pillars; in appearance it is a dusky, slightly raised patch, with a sharply defined red margin, the surface is covered by a delicate milky-white layer of superficial necrosis resembling a "snail-track" or, if rather thicker, looking as if it had been touched with nitrate of silver.

Diagnosis.—The appearances just described are so characteristic that they are of great help in the diagnosis of the general affection; if their nature should be misinterpreted, other secondary symptoms nearly always co-exist to establish the correct diagnosis.

Treatment.—General treatment quickly cures these secondary lesions, though they may reappear during the first two or three years. Of local treatment, abstinence from tobacco and alcohol is important, as are the careful use of a tooth-brush after every meal and the employment of a mouth wash, such as peroxide of hydrogen or chlorate of potash.

TERTIARY SYPHILIS

Tertiary lesions usually occur between the seventh and fourteenth year after infection, but may rarely be found within a few months or may make their appearance at any later time throughout the patient's life.

Symptoms.—Two principal forms may be described—(1) superficial ulcer, and (2) gumma.

1. The superficial ulcer may attack any part of the fauces, the posterior wall, tonsils, pillars or palate, a favourite site being the junction of the uvula with the edge of the soft palate. It has a flat base, with a smooth yellowish necrotic surface, and a well-defined red margin, devoid of swelling or infiltration, and of a peculiar "serpiginous" contour as though marked out by segments of a series of circles.

2. A gumma is a localised infiltration which rapidly breaks down and exposes a deeply excavated circular ulcer covered with a thick yellow slough. One favourite site is on the posterior pharyngeal wall above the level of the palate, and another on the posterior aspect of the soft palate; in the latter situation nothing is seen from the mouth except a general dusky swelling of the palate until perforation suddenly occurs and irremediable damage has been done. After severe gummatous ulceration the resulting cicatricial contraction may bind the palate to the pharyngeal wall and partly or completely shut off the naso-pharynx from the mouth.

Of subjective symptoms, dysphagia may be very severe; nasal obstruction is present when the naso-pharynx is occluded by swelling or scarring; the voice is altered to a dead tone when there is nasal obstruction, or to the characters of a cleft-palate articulation if a perforation of the palate has occurred.

Diagnosis.—From an ulcerating malignant growth the diagnosis may be

a matter of difficulty, especially as in syphilis the dysphagia may produce marked cachexia and loss of weight. The gummatous ulcer is excavated, covered by a dirty yellow adherent slough, its margin only moderately thickened, often overhanging, and surrounded by an area of deeply congested mucous membrane: the base of an epitheliomatous ulcer presents a nodular "cauliflower" aspect, and its edge is thick and everted; palpation with the finger is of great value, for the peculiar hardness of an epithelioma is highly characteristic. The superficial tertiary ulcer is usually easily distinguished from lupus, the ulcerations of which are surrounded by and dotted over with the characteristic granules, and the lesions of which occur on a pale mucous membrane, while manifestations of lupus are to be found elsewhere. Tuberculous ulceration of the fauces is superficial, but is more intensely painful than the superficial syphilitic ulcer, and is a terminal event in advanced pulmonary tuberculosis. Actinomycosis, when it attacks the region of the tonsil, closely resembles an ulcerating gumma, especially as it improves under administration of iodides: the detection of the characteristic yellow granules will lead to their microscopical examination and recognition.

Treatment.—The most energetic general treatment may be called for to prevent perforation of the palate or severe cicatricial deformity. Local treatment consists chiefly in the use of antiseptic mouth-washes and gargles. Orthoform by insufflation is helpful when there is dysphagia. The local application of 3 grains of calomel, sublimed by a spirit-lamp and insufflated daily from a glass tube, is to be recommended in severe cases of ulceration.

LUPUS AND TUBERCULOSIS

Lupus occurs most frequently in young women. It usually shows evidence of having spread from the nasal passages, and attacks first the uvula and soft palate, whence it spreads to the faucial pillars. It appears as a patch made up of minute reddish nodules, each containing the typical "apple-jelly" centre; the surrounding mucosa shows no sign of inflammation. A progressive superficial ulceration gradually occurs, and may cause destruction of the uvula and part of the soft palate, while elsewhere scarring becomes evident and may finally result in considerable deformity. The subjective symptoms are limited to a feeling of stiffness and discomfort. The diagnosis is generally easy from the characteristic appearance, the chronicity and the presence of lupus in the nares and on the skin. Syphilis is more rapid and does not spare the bony palate, which is never attacked by lupus. Lupus in the pharynx is far more amenable to treatment than in the nose, and may be expected to improve under the general anti-tuberculous régime of good food and open air; arsenic in full doses is very valuable, beginning with 5 minims of liquor arsenicalis three times a day, and increasing the dose gradually to 15 minims. Tuberculin has proved disappointing. Of local measures, massive patches of infiltration may be curetted, but multiple puncture with a fine galvano-cautery point is the most useful method.

Apart from the latent tuberculosis of the tonsils associated with cervical adenitis, which has been referred to under chronic tonsillitis, tuberculous

disease of the pharynx is a rare affection; it occurs as a late and terminal complication of advanced consumption. The onset is acute; the affected parts, especially the soft palate and faucial pillars, are covered with numerous tiny grey tubercles on a bright red mucosa which soon break down to form multiple superficial ulcers with a flat greyish yellow base. Pain is intense and swallowing becomes well-nigh impossible; treatment must be directed to alleviating the distress with insufflations of orthoform, lozenges of cocaine or morphine, hypodermic injections of morphine or heroin, and saline and nutrient enemata.

INNOCENT TUMOURS

Papillomata are fairly common on the uvula, soft palate and faucial pillars and tonsils. They are small pedunculated warty growths and are easily removed. A flat sessile papilloma in this region must be regarded with suspicion as a possible early epithelioma and should be promptly excised by an elliptical incision around the site of origin.

Angiomata occur in the soft palate. Removal is a formidable matter and must be performed by incisions wide of the tumour, but should be avoided when possible. Electrolysis and galvano-cautery or diathermy puncture are preferable methods of treatment.

Dermoid cysts, teratomata and mixed tumours, resembling those found in the parotid, are occasionally observed.

MALIGNANT TUMOURS

Epithelioma attacks the tonsils, soft palate or pharynx; the lower pharynx behind the cricoid plate is often affected in females and at a younger age than is usual in cancer. Sarcoma usually originates in the tonsil and the cervical glands are secondarily involved, though generally somewhat late in the disease. In the earlier stages, malignant tumours of the tonsil resemble simple hypertrophy and may easily escape attention; in many cases enlargement of the cervical glands is the first symptom, and in such the tonsil should always be remembered as a possible site of the primary disease; palpation with the finger is of great service in its detection, the firm hard feel of a tumour distinguishing it from simple enlargement. Malignant tumours of the tonsil and palate may be removed through the mouth by cutting wide of the growth with a knife and a pair of scissors, or with a diathermy knife; application of the latter to bone causes a slow aseptic necrosis, which may be made use of deliberately if the bone be involved. Splitting the cheek gives little or no more space and is unnecessary. Tumours situated lower down, in the pharynx, may be reached by the operation of lateral pharyngotomy. In this operation an incision is made along the anterior border of the sterno-mastoid, and joined by another below the jaw, and the pharynx opened in front of the carotid sheath; the mandible may also be divided. The cervical glands should be cleared out. Removal is only feasible when the growth is distinctly limited. Of palliative measures, diathermy may be used to remove the mass of the tumour, check fungation, and relieve symptoms. Oral hygiene, including the removal of all unhealthy

teeth, antiseptic sprays and insufflation of orthoform and anæsthesine for dysphagia, will do much to relieve the severity of the symptoms. Palliative tracheotomy, or gastrostomy, if required, should not be too long deferred.

The technique of the application of radium to tumours of the throat has made great advances in the last few years, and has produced apparent cure in some cases and diminution of the growth in many others. Two methods are employed, either separately or in conjunction, namely, the implantation of radium needles or of tiny capsules containing radium emanation, and the application of a wax collar containing radium plates. The technique of deep X-ray therapy has also improved greatly, damage to superficial structures being avoided by adequate screening and by "cross-fire" methods. Good results have been reported, though for epithelioma it appears to be less helpful than radium.

HAROLD S. BARWELL.

DISEASES OF THE ŒSOPHAGUS

NERVOUS DISORDERS OF THE ŒSOPHAGUS AND DEGLUTITION

PARALYSIS OF DEGLUTITION MUSCLES

When the soft palate is paralysed, as in diphtheritic neuritis, the nasopharynx cannot be shut off from the rest of the pharynx during the act of deglutition. Part of the food is consequently propelled into it instead of into the œsophagus, and fluids may escape through the nostrils. At the same time the normal rise of pressure in the pharynx does not occur, and dysphagia results. In bulbar paralysis the tongue, palate and pharyngeal muscles are paralysed, and swallowing becomes impossible.

Unilateral lesions of the vagus do not affect deglutition, but bilateral lesions of the bulbar nuclei or of the peripheral nerves cause dysphagia, as the striated muscle fibres of the upper third of the œsophagus lose their tone and contractility, though the automatic activity of the unstriated fibres of the lower two-thirds is unaffected. When the irritability of the medulla is greatly depressed, as in deep coma, a similar dysphagia results.

SPASM OF THE ŒSOPHAGUS

Ætiology.—Spasm of the œsophagus occurs most frequently as a local reflex complicating organic disease, the most common of which is cancer. It forms the most characteristic symptom of hydrophobia. Hysterical spasm may occur at the entrance to the œsophagus in suggestible individuals, but it is rarely sufficient to cause serious dysphagia.

Treatment.—Hysterical spasm can be relieved by the passage of a bougie to show that the passage is clear, but the underlying psychological factors which caused the symptom to develop require treatment by psychotherapy. Some relief to the spasm caused by organic disease is gained by the use of belladonna, and the food should be fluid and chemically unirritating.

ACHALASIA OF THE PHARYNGO-ŒSOPHAGEAL SPHINCTER
(PLUMMER-VINSON SYNDROME)

Pathology.—In the voluntary initiation of swallowing, the food is thrown to the back of the pharynx. The sphincter at the junction of the pharynx and œsophagus, which is normally closed, then relaxes and allows the bolus to enter the œsophagus, along which it is carried by active peristalsis. In this condition the sphincter does not relax, so that swallowing can only occur with difficulty. As it is almost always associated with atrophic streptococcal inflammation of the mucous membrane of the tongue, which spreads back to the mouth of the œsophagus, it seems reasonable to suppose that the latter has led to inflammation and degeneration of Auerbach's plexus in the region of the sphincter, exactly analogous to what occurs in achalasia of the cardia. The toxæmia resulting from the streptococcal infection leads to secondary anæmia and sometimes splenomegaly.

Symptoms.—The patient gradually finds difficulty in initiating the process of swallowing, especially solids. This is associated with glossitis of the kind often associated with Addison's anæmia, and progressive anæmia of a secondary non-Addisonian type. The spleen is often enlarged. The X-rays reveal no abnormality, and the œsophagoscope shows nothing more than an atrophic inflammation of the mucous membrane in the neighbourhood of the sphincter.

Treatment.—Dental sepsis, which may have led to the glossitis, should be thoroughly treated, and a hydrogen peroxide mouth-wash should be frequently used. A mercury bougie should be introduced into the œsophagus and passed from time to time until the dysphagia disappears. The anæmia responds to treatment with iron and arsenic, but in severe cases transfusion is required. Liver diet is without effect.

ACHALASIA OF THE CARDIA: SO-CALLED CARDIOSPASM

Ætiology.—Achalasia of the cardia may begin at any age, but most commonly in adults, and males and females are equally affected.

Pathology. The hypertrophy of the muscular coat of the œsophagus which is always present in this condition indicates that violent efforts must have been made to overcome some obstruction. As no organic obstruction is ever found, the cardiac sphincter after death being of normal size, it is clear that the obstruction must be functional. Since the suggestion was first made that this was due to a spasm of the cardiac sphincter, the condition has been generally known as cardiospasm. As the symptoms may be present without intermission for many years before death, a considerable degree of hypertrophy of the cardiac sphincter would result from the long-continued spasm. In very few autopsies, however, has there been any hypertrophy, and in a case in which the cardiac sphincter, which is normally about 1 inch long and corresponds with the whole of the abdominal œsophagus, was exposed by operation, the muscle was found to be unusually thin.

I believe that the obstruction is due to achalasia (α , not; χαλᾶω, I relax), or absence of the normal relaxation of the cardiac sphincter, which should

occur when each peristaltic wave reaches it (Figs. 14 and 15). Food stagnates in the œsophagus, which dilates as more and more collects in it; the distension of the œsophagus acts as a powerful stimulus to peristalsis, which

is excessively violent and continues at intervals throughout the day. This is the cause of the hypertrophy.

Further evidence that the condition is due to achalasia rather than spasm is afforded by the fact that, although strong peristaltic waves are unable to overcome the obstruction, the weight of an indiarubber tube filled with mercury is sufficient to cause it to drop through the cardia into the stomach, the actual passage through the cardia being often inappreciable to the hand which holds the mercury tube, and the tube can be withdrawn with equal ease; it is not gripped, as the finger

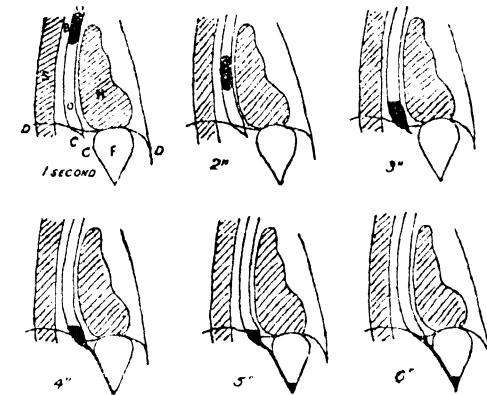

FIG. 14.—Diagrams of normal swallowing as seen with the X-rays in successive seconds. OO, œsophagus; B, bolus of food; CC, cardiac sphincter; DD, diaphragm; S, spine; H, heart; F, gas-containing fundus of stomach.

is gripped when it enters or is withdrawn from a spasmodically contracted anal sphincter.

Rake and Stokes have shown that the condition is due to degenerative changes occurring in Auerbach's plexus between the circular and longitudinal muscular coats of the cardiac sphincter. The degeneration is a sequel of inflammation, which spreads from the mucous membrane from a primary œsophagitis, or results from blood-borne infection.

The dilated œsophagus may be able to hold as much as a pint, and its circumference may exceed 6 inches.

Symptoms.—Achalasia of the cardia generally develops gradually, a slight attack, lasting for a day or two, being followed by a period of freedom for a few days, or even several weeks or

months; other attacks then occur at gradually shorter intervals, until finally the condition becomes permanent. The patient feels as if the food "sticks"; he often recognises that the obstruction is beneath the lower end of the sternum, but sometimes the sensation is felt in the upper part or middle

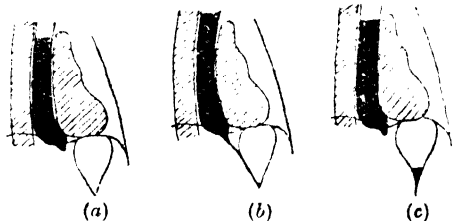

FIG. 15.—Drawings from a case of dilated œsophagus secondary to achalasia of the cardia. (a) Dilated œsophagus filled with an 8-inch column of opaque food; sphincter closed. (b) Opaque food passing into stomach through sphincter which has opened after additional food has raised column in œsophagus above 8-inch height. (c) Return to condition of (a) after excess of food over the 8-inch column has entered stomach.

of the chest. Sometimes actual pain is produced. Salivation occurs in every case.

As a rule the patient voluntarily relieves his discomfort within a few minutes of finishing a meal by bringing up the greater part of what he has eaten mixed with saliva. He can generally do this quite easily, but occasionally requires to produce a vomiting reflex by tickling his throat; in neither case is there any nausea.

The weight of the column of food in the dilated œsophagus after a meal is sufficient to force a small proportion of the fluid present through the cardia as a very narrow stream; but as soon as the weight of the column falls below a certain point, generally about 8 inches, or the individual lies down, the pressure becomes insufficient, and the flow ceases (Fig. 15). Consequently food stagnates in the œsophagus for an indefinite period, and a considerable quantity can be removed from it even after a fast of twenty-four hours.

The œsophagoscope shows that the entry to the cardiac sphincter, which is approximately at the level of the diaphragm, is completely closed. The mucous membrane may be normal, but it is often red and inflamed, especially in the lowest part of the œsophagus, and there may be superficial erosions, which are secondary to the stasis.

The general health at first remains perfectly good in spite of the fact that weight is rapidly lost. After a certain amount of weight is lost, a condition of equilibrium develops; though extremely small quantities of food reach the stomach, the patient loses no more weight, and though he is less strong than formerly, he may continue to live in this condition for many years and reach old age.

Diagnosis.—The patient's description of his symptoms is generally so characteristic that a diagnosis of œsophageal obstruction can be made with a considerable degree of probability. This is confirmed by means of an X-ray examination, which must in the early intermittent stage be made during an attack, when the situation of the obstruction at the cardiac orifice is at once apparent. It is next necessary to ascertain whether this is due to achalasia or to cancer, as non-malignant strictures are extremely rare, except as a result of caustic poisoning, when a history is generally obtainable and the obstruction is found to extend for some inches upwards instead of being strictly confined to the cardiac sphincter. The intermittent character of the early attacks, the absence of serious constitutional symptoms in spite of rapid loss of weight, the comparatively early age at onset with many patients, and, in cases in which an early diagnosis has not been made, the long duration of the illness and enormous dilatation of the œsophagus point to achalasia rather than to growth. Occult blood is generally present in the stools in cancer, but never in achalasia of the cardia. The even outline of the shadow and the localisation of the obstruction to the cardiac sphincter in achalasia differ from the more irregular outline and the more extensive area of obstruction in cancer. Further evidence is the ease with which a mercury tube passes through the cardia in achalasia in contrast with the complete obstruction offered to its passage by a growth.

Prognosis.—If the condition is recognised at the onset of symptoms, a permanent cure often results from treatment, but if treatment is only instituted when the obstruction has become continuous and the œsophagus greatly dilated, cure as distinct from mere relief of symptoms is less likely

to be obtained. In the absence of treatment death has occurred at an early stage in very acute cases; but more often the patient survives for a considerable period, even for 40 years.

Treatment.—The simplest and most effective treatment is by means of a mercury tube. The tube has a rounded end with no holes in it, the diameter of the larger being 24-gauge. It is half-filled with mercury, the upper end being closed. The tube drops through the cardia; it requires no pushing, and can be easily managed by the patient himself. It is kept in position for a quarter of an hour on each occasion at first, but later it can be withdrawn directly after it has entered the stomach. The patient feels relieved, and realises that "the passage is clear" as soon as it is withdrawn. It should be passed immediately before meals; the food then enters the stomach without difficulty. In very early cases the tube may only need to be passed once. Generally, however, the tube has to be passed before each meal at first, then once a day, and gradually less often, till finally it is only used at rare intervals when the patient feels that some slight obstruction is returning. In chronic cases, which are always associated with secondary œsophagitis, the patient should make an effort to evacuate any food which is still present in the œsophagus a quarter of an hour after the end of each meal. Whether he is successful or not, he should then drink about 5 ounces of water, and after a minute evacuate this; the dilated œsophagus is thus kept clean, and the œsophagitis is rapidly overcome. In the only case I have seen in which the mercury tube did not give sufficient relief, and forcible distension with a rubber bag proved useless, great improvement followed longitudinal division of the cardiac sphincter in the same way as the pyloric sphincter is divided in Ranmstedt's operation for hypertrophic stenosis in infants.

WATERBRASH

Ætiology.—Waterbrash may persist for years without any other evidence of indigestion, but it is generally associated with some form of functional or organic gastric disease, and particularly with conditions, such as duodenal ulcer, which are associated with hyperchlorhydria, probably because they also give rise to reflex hypersecretion of saliva.

Symptoms.—At a certain interval after a meal, which varies in different cases, but is fairly constant for each individual, an uncomfortable sensation of constriction, which may amount to severe pain, is felt deeply beneath the lower end of the sternum. This may be accompanied by profuse salivation. Relief occurs only on bringing up a few mouthfuls of clear fluid, which is generally described by the patient as being like water, though it sometimes contains a good deal of mucus. The fluid rises into the mouth with little or no effort and without nausea.

The fluid must come from the œsophagus and not from the stomach, as even when the previous meal was large and has only been finished within an hour, no food is present in the regurgitated material, which is alkaline in reaction and has all the characters of pure saliva.

When the flow of saliva is moderately excessive, it runs down the œsophagus without the patient's knowledge and without the aid of actual swallowing; the cardiac sphincter is naturally closed, and the fluid therefore collects above it in the lower end of the œsophagus. The morning vomiting

of alcoholic individuals is due to a similar process, although it is accompanied by more violent vomiting efforts. In this case the fluid consists of saliva mixed with a considerable proportion of pharyngeal and œsophageal mucus, as catarrhal pharyngitis and œsophagitis are frequently associated with the catarrhal gastritis of alcoholic patients.

Treatment.—Waterbrash requires no special treatment, as it is rapidly relieved by adequate treatment of the primary condition.

DIVERTICULA OF THE PHARYNX AND ŒSOPHAGUS

Ætiology and Pathology.—Diverticula may develop from the anterior wall of the middle third of the œsophagus by the traction resulting from adhesions between inflamed glands near the bifurcation of the trachea and the wall of the œsophagus; these “traction diverticula” are generally less than an inch in depth and rarely give rise to symptoms. A diverticulum, which has given rise to no symptoms, is occasionally discovered at the lower end of the œsophagus during a routine radiographic examination. Its origin is generally obscure, but in one of the three cases I have seen it was associated with achalasia of the cardia.

Pressure diverticula are rare, but are of considerable clinical importance. They occur only in adults, and always develop at the muscular gap on the posterior wall of the pharynx between the upper and lower divisions of the inferior constrictor of the pharynx, at the level of the cricoid cartilage. They are really diverticula of the pharynx and not of the œsophagus, though they have generally been described as œsophageal. The lower division of the inferior constrictor of the pharynx forms a sphincter surrounding the entrance to the œsophagus. It is closed at rest, but opens during each act of deglutition the moment the food reaches it. If for any reason it does not open, the food is forced against the weak spot on the posterior wall of the pharynx immediately above the sphincter. A pouch of mucous membrane may thus be formed; it becomes progressively larger towards one side, owing to the accumulation of food in it, until it may finally measure as much as 5 inches in depth and be large enough to contain over a pint of fluid, in which case it may extend into the posterior mediastinum. Its wall is formed of mucous membrane and submucous tissue without any muscular covering.

Symptoms.—Diverticula of the pharynx sooner or later cause progressive dysphagia. The patient complains of obstruction in the neck when he swallows, and a small quantity of food is regurgitated at varying intervals after meals. As the sac increases in size, the symptoms become more marked owing to obstruction of the œsophagus by the distended diverticulum, which finally forms a prolongation of the pharynx, the œsophagus opening as a transverse slit out of its anterior wall. Increasing quantities of food are brought up, mixed with a large amount of mucus, and food eaten several days before may be recognised. The patient becomes steadily more emaciated. Distension of the sac often causes pain, which is relieved when it is emptied. An irritable cough is often present, and dyspnoea may result from pressure on the trachea. A large diverticulum containing food may form a

visible tumour in the neck, generally on the left side, which can be emptied by pressure, the food returning into the pharynx.

The size, shape and exact position of the diverticulum can be recognised with the X-rays after a barium meal.

Treatment.—The only satisfactory treatment of a pharyngeal diverticulum is excision.

ACUTE OESOPHAGITIS

Ætiology.—Acute catarrhal oesophagitis may occur in various acute infective diseases, such as scarlet fever, and it may also complicate cancer of the oesophagus and spread from acute pharyngitis. In 5 per cent. of fatal cases of diphtheria the inflammation has spread from the fauces into the oesophagus, and in very rare cases the membrane extends as far as the cardia. The impaction of a foreign body in the oesophagus may cause local suppuration. Acute inflammation results from swallowing boiling water or corrosive poisons, taken by accident or in attempted suicide; owing to the delay caused to the passage of the oesophageal contents by the narrow cardiac sphincter, the lower end is the part most affected, the upper extremity being next most seriously injured.

Symptoms.—In mild cases there may be no symptoms, but more or less dysphagia is generally present; in severe cases deglutition is so painful that the patient may be afraid to swallow his saliva or relieve his urgent thirst by drinking. There may also be constant pain beneath the sternum. Attempts to swallow often prove unsuccessful owing to reflex spasm, the food being brought up at once. Mucus is expectorated, together with blood and pus in severe cases.

Treatment.—In severe cases nothing should be given by mouth, but saline solution must be injected by the rectum or under the skin. Morphine is required for the pain. When the pain begins to subside, olive oil in half-ounce doses can be given by the mouth, and after a short time fluids may be sipped after each dose of oil. Solid food should not be given until swallowing no longer causes pain. If an X-ray examination shows that a stricture is developing, bougies should be regularly passed as soon as the acute inflammation has subsided; but in spite of their use complete obstruction necessitating gastrostomy is likely to occur in severe cases following corrosive poisoning.

CHRONIC OESOPHAGITIS

Ætiology.—Chronic oesophagitis results from the constant swallowing of irritants, the most important of which are strong alcoholic drinks, and from septic conditions of the teeth and naso-pharynx. It is also a common sequel of stasis of food in the oesophagus, especially that caused by achalasia of the cardia.

Symptoms.—As the condition is almost always associated with chronic pharyngitis and gastritis, it is generally impossible to isolate the symptoms of one of them from the others. The morning vomiting of alcoholics, which so often precedes the development of symptoms due to the hepatic condition in cirrhosis of the liver, is to a great extent caused by oesophageal catarrh.

Treatment.—The œsophagitis quickly disappears when the sources of irritation are removed by the patient becoming teetotal and all septic foci in the mouth being removed.

NON-MALIGNANT STRICTURE

Ætiology.—Stricture of the œsophagus is in rare cases congenital; the middle part of the œsophagus may be represented by a fibrous cord, or the lower part may open into the trachea or into one of the bronchi. Acute traumatic œsophagitis is the chief cause of fibrous stricture, but it may also very rarely result from the healing of a simple ulcer, from the acute œsophagitis of fevers, and from syphilis.

Pathology.—Cicatricial stenosis generally occurs at the lower end of the œsophagus, but sometimes also at the top, and occasionally at the bifurcation of the trachea.

Treatment.—Fibrous strictures must be dilated by the passage of bougies of gradually increasing size. In severe cases, they should be guided into the stomach by a piece of string, previously swallowed, threaded through their lower end. There is a constant tendency to recur, so a bougie must be passed at regular intervals. I have seen a well-developed boy of 10, who had been fed entirely through a gastrostomy, which had been made a few days after birth on account of congenital stricture of the œsophagus.

CANCER

Ætiology.—Primary cancer of the œsophagus occurs with about half the frequency of primary cancer of the stomach. Over 70 per cent. of cases of cancer of the œsophagus occur in men, but cancer of the lower end of the pharynx is most frequent in women.

Pathology.—A large proportion of growths of the œsophagus are epitheliomata. They are about equally common at the upper extremity of the œsophagus, at the level of the bifurcation of the trachea and at the cardia, these being the three narrowest parts, the mucous membrane being consequently most subjected to friction by coarse food. It is often impossible to say whether an epithelioma at the upper end of the œsophagus is a primary growth of the pharynx, from which it has spread into the œsophagus, or whether it is a primary growth of the œsophagus and has spread into the pharynx. Ulceration occurs at an early stage. Accumulation of food in the œsophagus above the obstruction leads to progressive dilatation, and the efforts of the œsophageal musculature to overcome the obstruction result in hypertrophy, but the dilatation and hypertrophy are comparatively slight, except in cancer of the lower end, as when the obstruction is higher up vomiting occurs so quickly that very little food can accumulate.

Symptoms.—Dysphagia is almost always present and is the first symptom in a large majority of cases. Most frequently a patient in perfect health one day experiences a slight discomfort on swallowing; soon he notices that his food seems to stick for a moment before passing on into his stomach.

The difficulty becomes slowly but steadily more marked, with rare intermissions lasting for a few meals or at most for a few days. The patient often manages to swallow his food by chewing more thoroughly, by taking smaller mouthfuls, and by drinking after each mouthful is swallowed; but more and more effort is required, until after a period, which is generally between 1 to 4 months, but may be as long as a year, solid food ceases to pass at all and is brought back into the mouth a few seconds later. The patient generally localises the position of obstruction correctly, but he sometimes thinks that it is in the upper third when it is really in the lower third. The difficulty in swallowing continues, until after an average of 8 months there is complete obstruction to the passage of fluids as well as solids.

Pain only occurs in 40 per cent. of cases; it is most frequently absent when the growth is in the lowest third of the œsophagus. It occasionally begins a few days before or simultaneously with the dysphagia, but it more commonly is not noticed until the latter has been present for 1 or 2 months. The pain may only be present during deglutition, disappearing as soon as the food passes the obstruction. It is situated at the level of the obstruction, and often passes through to the back.

Regurgitation of food almost always occurs sooner or later; it generally begins between 1 and 2 months after the onset of symptoms and is rarely delayed as long as 6 months.

When the growth is situated in the upper third of the œsophagus the food is violently ejected out of the mouth, or even from the nose after a coughing effort. When the middle or lower third is involved the food regurgitates without effort into the mouth, and the regurgitation may occur immediately after meals. If the œsophagus is dilated, food may be regurgitated any time up to 2 hours after being swallowed. The food is completely undigested and always contains mucous saliva, often in considerable quantity. Regurgitation of saliva only occurs when the obstruction is sufficient to interfere with the swallowing of fluid as well as of solid food. Salivation may be continuous. The regurgitation of the contents of the dilated œsophagus gives relief to any discomfort or pain which is present at the time. The regurgitated material sometimes contains blood and pus, and may be very foul; occasionally several ounces and in rare cases a large quantity of blood is vomited.

Progressive emaciation occurs owing to the small amount of food which is taken, and when obstruction is complete the loss of weight is very rapid. The appetite may remain good, and hunger may be very distressing in the early stages, but this becomes less marked as the disease progresses. Severe thirst, with dryness of the mouth, is sometimes present, and fœtid breath is common when there is extensive ulceration. Small hard glands are often felt in the neck, especially just above the inner end of the clavicle and beneath the lower jaw.

The vagus or recurrent laryngeal nerves, especially of the left side, may be involved, and one, or rarely both, vocal cords may consequently be paralysed. Pressure on the cervical sympathetic may cause contraction of the pupil, with slight enophthalmos and narrowing of the palpebral fissure on the affected side. Compression of the trachea or the main bronchi by the tumour or by secondary glands may cause hoarseness, coughing and dyspnoea. Perforation into the trachea or a bronchus gives rise to a paroxysm

of coughing and dyspnœa whenever food is swallowed, and death from broncho-pneumonia or gangrene of the lung is likely to occur. Perforation into the pleural cavity may produce empyema, but a serous pleural effusion may develop without perforation.

Diagnosis.—In a large proportion of cases it is possible to make a definite diagnosis from the history and from the information obtained with the X-rays, which should always be used without delay in cases of dysphagia. Before giving the opaque meal the thorax should be examined from every direction in order to exclude an aneurysm, although in the very rare cases in which this causes dysphagia other more characteristic symptoms generally make the diagnosis clear. Occasionally a growth of the œsophagus throws a shadow with the X-rays, but this is rarely at all obvious until the symptoms have been present for a considerable time; more frequently secondary deposits in glands form abnormal shadows in the posterior mediastinum. With the aid of an opaque meal the X-rays show the exact position of any narrowing of the lumen of the œsophagus, the degree of dilatation above the obstruction, and the degree of obstruction, but spasm may cause the latter to appear complete though it is found to be incomplete after death.

The diagnosis of a growth of the cardia from achalasia has already been considered (p. 509). The presence of hard glands in the neck makes the diagnosis of cancer extremely probable in cases of œsophageal obstruction. In the rare cases in which the history and the X-rays leave the diagnosis in doubt, and especially in early cases, an examination should be made with the œsophagoscope, by means of which the exact nature of the obstruction can generally be recognised.

There is rarely much difficulty in diagnosing between an elipitheoma of the cardiac end of the œsophagus, which may spread upwards but never spreads downwards into the stomach, and a primary carcinoma of the cardiac end of the stomach, which almost invariably involves the cardiac orifice sooner or later. With the former the dysphagia is the first symptom: with the latter anorexia, pain after food, vomiting, loss of weight and strength, and increasing pallor appear before the dysphagia, and the vomiting is at first acid in reaction and only becomes alkaline later when the food can no longer reach the stomach. The X-rays show a filling defect in the stomach when the tumour is gastric in origin, and sooner or later a mass can be felt high up under the left costal margin.

Prognosis.—Death occurs between 2½ months and 2½ years after the onset of symptoms, the most common period being between 6 and 12 months. It is most frequently due to broncho-pneumonia, exhaustion from starvation being the next most common cause.

Treatment.—The radical treatment of cancer of the œsophagus by excision of the growth has very rarely been successful, but with the recent advances in thoracic surgery the outlook is becoming more hopeful, as the diagnosis can generally be made at a much earlier stage of development than in cancer of the stomach or colon.

The first question to consider in most cases is whether a gastrostomy should be performed; the operation saves the patient from starvation, and if it is not postponed until too late the immediate mortality is small. It is rare, however, for the patient to survive very long, the results differing in this

way from those of gastro-jejunostomy for pyloric cancer and colostomy for intestinal growths. When the disease appears to be progressing slowly, and for any reason the use of Souttar's spiral metal tube is impracticable, a gastrostomy or jejunostomy should be advised as soon as difficulty is experienced in swallowing fluids.

When the growth involves the centre of the œsophagus, Souttar's tube should be introduced through an œsophagoscope, if necessary after preliminary dilatation of the stricture by bougies. Its lower end reaches beyond the lower extremity of the growth, whilst the upper funnel-shaped end rests on its proximal margin. The tube can be left *in situ* until the end.

Treatment by radium and deep X-rays sometimes prolongs life to a slight extent, but no case of cure has been recorded.

The food should be fluid or semi-fluid, and should be taken in small quantities at frequent intervals. Some patients are able to swallow raw eggs whole, as the egg white appears to relieve spasm so that the egg passes intact into the stomach. A dessertspoonful of olive oil taken before each feed often helps its passage through the stricture. When swallowing is painful, an injection of a small dose of atropine with morphine should be given half an hour before each feed.

ARTHUR F. HURST.

DISEASES OF THE STOMACH

EXAMINATION OF THE STOMACH

MOTOR FUNCTIONS

(a) **SIZE, SHAPE AND POSITION.**—*Inspection* of the abdomen may reveal the outline of the stomach in thin patients, especially if pyloric obstruction has led to excessive activity of peristalsis. *Palpation* under similar circumstances often makes it possible to feel the lower border of the stomach. It may also reveal the presence of a tumour, the size, shape, position and mobility of which should be estimated. When the gastric contents can be splashed with unusual ease on abdominal palpation or on shaking the patient, the approximate size and position of the stomach can be determined from the area in which the splash is best heard with a stethoscope. *Percussion* may give some idea as to the quantity of gas in the stomach, but it cannot help in the determination of its size, shape or position; *auscultatory percussion and friction* have been shown by means of the X-rays to be quite valueless for examining the stomach.

X-rays.—The size, shape and position of the stomach can be readily and accurately determined, both in the vertical and horizontal position, by means of the X-rays after a meal of porridge containing 3 ounces of barium sulphate. By palpation during the screen examination, its mobility can be investigated, and the presence of adhesions and areas of tenderness recognised.

(b) **TONE.**—*Splashing and succussion* can be obtained in an individual with relaxed abdominal muscles and a stomach with normal tone. They give no information as to the presence of atony.

X-rays.—Owing to the adaptation of the stomach to the volume of its contents, there is little difference in the upper level of the semi-fluid chyme as seen with the X-rays in the erect position whether the volume be 5 ounces or 2 pints, and the greater curvature is only slightly depressed as the stomach is gradually filled. When the stomach is hypotonic, this adaptation to the volume of its contents does not occur; the food drops to the most dependent part, the upper level of the contents slowly rising and the greater curvature becoming more dependent as the volume increases. It is very important to distinguish this condition from the distension without hypotonus caused by the continuous presence of fluid or fluid and food in the stomach in pyloric obstruction or an ulcer near the pylorus. In this condition the opaque meal appears to fall to the bottom of a large stomach, but closer investigation shows that it is really falling through a large quantity of fluid already present in the stomach, which throws no shadow, but the upper horizontal level of which can be recognised at the normal distance below the diaphragm. If the examination is repeated after emptying the stomach of its resting contents with a stomach tube, the tone is found to be normal and no dilatation is present.

(c) PERISTALSIS.—*Inspection and palpation.*—In unusually thin women normal peristalsis is occasionally visible, but in the majority of cases the presence of visible peristalsis indicates organic pyloric obstruction. The patient should be examined immediately after a meal; in doubtful cases peristalsis can be rendered more obvious by massage. At a stage preceding that in which peristalsis is visible, it may often be felt as a periodic hardening, if the hand is kept for some time gently pressing upon the right side of the abdomen a little above the umbilicus.

X-rays.—Deficient peristalsis cannot be recognised with certainty by any method except the X-rays. In pyloric obstruction the peristaltic waves can be seen to commence in the fundus instead of in the centre of the body, and to lead to unusually great depression in the outline of the organ at a period considerably earlier than that in which it becomes visible through the abdominal wall. Reversed peristalsis generally indicates organic pyloric obstruction, but I have also seen it in cases of chronic appendicitis and lesser curvature ulcer with gastric stasis but no obstruction. Irregular peristalsis, and especially peristalsis which begins in the normal position but disappears as it passes along the greater curvature before the pylorus is reached, is very suggestive of malignant infiltration.

(d) RATE OF EVACUATION.—*Splashing and succussion.*—The stomach should be completely empty in less than 6 hours after dinner. If, therefore, splashing and succussion can be elicited 6 hours after such a meal, it may be concluded that stasis is present. This may be due either to atony if the erect position has been maintained, feeble peristalsis, or pyloric obstruction. If, however, these signs are present 12 hours after dinner—at 8 a.m., for example, if dinner was taken at 8 p.m.—organic pyloric obstruction is present, unless there is an ulcer in the neighbourhood of the pylorus, as this may cause continuous secretion of gastric juice, so that the stomach is never empty, although there is no great delay in the passage of the food into the duodenum.

Stomach-tube.—When the symptoms or physical signs suggest the possibility of pyloric obstruction, it is essential to investigate the case by means of a stomach-tube. A dinner, which should include meat and lettuce or celery,

sweets and a dozen raisins, is given at 9 p.m., and Senoran's evacuator is passed at 9 a.m., nothing having been taken in the interval. After removing the fasting contents of the stomach, it should be thoroughly washed out with water. In normal individuals less than 50 c.c. of colourless or bile-stained gastric juice are found; no gross food residue is present, and even microscopically no meat fibres and only occasionally a little vegetable debris, together with a few leucocytes and bacteria derived from the mouth, are found. In atonic dilatation the stomach is always empty 12 hours after a meal. In chronic gastritis, especially when due to alcohol, a small quantity of thick alkaline fluid, consisting mainly of swallowed saliva and pharyngeal and oesophageal secretion, may be present. In the continuous secretion which results from an ulcer near the pylorus, even in the absence of obstruction, a small quantity of very acid fluid without any food residue is found. When an ulcer has led to organic obstruction, starch granules and vegetable debris, but no meat fibres, are present, in addition to some acid fluid; the quantity of the latter is much increased if the ulcer is still active, as hypersecretion then occurs in addition to stasis. Large numbers of budding yeasts and sarcinae are found microscopically. In malignant obstruction the gastric contents are thicker and contain debris of both vegetable and animal food; free hydrochloric acid is absent, and lactic acid is often present. Many bacteria, but comparatively few yeasts and sarcinae, are present.

X-rays.—Careful examination before the opaque meal is given may show that a considerable quantity of fluid is present in the fasting stomach; its upper horizontal level can be seen under the gas in the fundus, and splashing can be observed if the patient shakes himself. If, after an opaque meal, the shadow of the stomach is still visible 6 hours after a barium meal, nothing having been taken in the interval, stasis is present; after 9 hours it is probably, and after 12 hours it is certainly, due to organic pyloric obstruction.

CHEMICAL FUNCTIONS

The chemical functions of the stomach can only be adequately investigated by means of a test-meal. The old-fashioned test-breakfast is less satisfactory than the modern fractional test-meal, which provides information respecting the characters of the resting-juice and post-prandial secretion, the secretory response throughout the period of gastric digestion, the secretion of mucus, the regurgitation of bile and duodenal contents, and also allows of an accurate estimate of the rate of emptying. The patient, who should have taken no food since the night before, swallows the tube (the best form being Ryle's modification of that introduced by Einhorn) in the morning. The resting-juice is withdrawn and measured, its bile and mucus content noted, and the free and total acidity determined; the presence of gross food residue or a positive starch reaction is diagnostic of pyloric stenosis. After withdrawal of the resting-juice the patient drinks 1 pint of oatmeal gruel, and small specimens of gastric contents are withdrawn with a syringe at intervals of a quarter of an hour until the stomach is empty. The free and total acidity in each specimen is estimated, Topfer solution and phenolphthalein being the respective indicators customarily employed. The time of disappearance of the starch, which may precede complete emptying, is deter-

mined by adding iodine to the successive samples. The free and total acidity are plotted as curves upon a chart.

One hour after the beginning of the meal a larger fraction (20 c.c.) should be removed for the quantitative estimation of active hydrochloric acid, i.e. the quantity of free and organically combined hydrochloric acid. Two equal portions of filtered gastric contents, to the first of which excess of sodium carbonate solution is added, are evaporated to dryness and ignited at a low red heat until charring is complete. The chlorides are estimated in each portion by Volhard's method, the first giving the total chlorides and the second the mineral chlorides, the difference being the active hydrochloric acid, the normal quantity of which varies between 0.1 to 0.2 per cent.

Lactic acid may be recognised by Uffelmann's reagent (30 c.c. 1 per cent. carbolic acid with a few drops of ferric chloride solution), which it changes from blue to canary yellow. An ethereal extract of the gastric contents must be used, 5 c.c. of gastric contents being shaken with 30 c.c. of ether.

Microscopical examination of the resting-juice may reveal the presence of red corpuscles, leucocytes, very rarely fragments of mucous membrane or growth, sarcinæ in non-malignant pyloric obstruction, and the Boas-Oppler bacilli in malignant cases. The discovery of leucocytes is only of importance if their number is obviously in excess of the number present in a specimen of spittle obtained at the same time, as in the large majority of cases they have all been swallowed with saliva. True excess of leucocytes indicates the presence of gastritis or carcinoma. When the resting-juice or some or all of the fractions of a test-meal are red owing to the presence of blood, a bleeding ulcer or carcinoma is present. Specks of blood in otherwise blood-free specimens are generally of no importance, being due to accidental contamination.

Occult blood.—Apart from the obvious presence of blood in the stools (melæna), "occult blood" may be recognised by chemical means (see p. 562).

ARTHUR F. HURST.

FUNCTIONAL DISORDERS OF THE STOMACH

MOTOR DISORDERS

ATONY ; ATONIC DILATATION

Ætiology.—Atony of the stomach, together with the dilatation to which it gives rise, is often diagnosed on insufficient grounds, but the X-rays have shown that it is in fact a comparatively rare condition. It is most commonly associated with neurasthenic dyspepsia, and it is also an occasional sequel of infections, especially influenza and typhoid fever, and of all conditions leading to malnutrition.

Symptoms.—The chief symptom is an uncomfortable sensation of fullness during and after meals, which leads to progressive diminution in the amount of food taken, the patient thereby hoping to diminish his discomfort, but actually increasing the atony by starving his nervous and muscular tissues. In uncomplicated cases pain and vomiting are never present.

Diagnosis.—The diagnosis of functional atonic dilatation depends, firstly, upon the estimation of the size and tone of the stomach, and, secondly, upon its differentiation from the atony and dilatation which occur in organic pyloric obstruction when the compensatory hypertrophy proves insufficient.

Treatment.—Rest in the recumbent position is not only valuable for the exhausted nervous system, but it also places the atonic stomach in a condition of mechanical advantage, especially if the patient lies on his right side. In slight cases it is only necessary to lie down for an hour after each meal; in advanced cases the patient should at first remain in bed all day, and should lie on his right side while he eats and for an hour after each meal.

An ordinary mixed diet should be given, but the bulk of the meals should be as small as is compatible with the provision of a proper amount of nourishment, and fluids should be drunk only when the stomach is empty. A glass of milk may be taken on rising in the morning, a glass of milk an hour before lunch, one or two cups of tea at 5 p.m., and a glass of milk last thing at night. In severe cases, no fluid at all should be drunk for some days; the meals should be quite dry, and saline solution given by rectum.

Strychnine is often of use, as it improves the appetite, though it is doubtful whether it has any direct effect upon the gastric tone, and it should not be given to patients suffering from severe neurasthenia. It may be combined with dilute hydrochloric acid (15 minims), if there is deficiency in gastric secretion, and with a bitter such as gentian, which stimulates the appetite. In excitable patients, and in patients who find it difficult to lie quietly in bed for a sufficient period, small doses of bromide and arsenic should be given.

In uncomplicated cases, lavage is likely to do more harm than good, but in severe cases complicated by chronic gastritis, lavage with small quantities of plain water may be of use. Gastro-enterostomy is absolutely contra-indicated.

ACUTE DILATATION

Ætiology.—After abdominal operations with or without peritonitis, and much less frequently in the course of acute and chronic infections, especially pneumonia, the stomach suddenly becomes greatly dilated owing to a complete loss of tone. The acute dilatation leads to obstruction of the duodenum by the mesentery at the point where the latter crosses it, so the dilatation is greatly increased.

Symptoms.—The abdomen is very distended, large quantities of dark but not fæcal fluid are vomited, and the patient rapidly becomes very collapsed.

Treatment.—The stomach should be kept empty by aspirating through a Ryle tube kept continuously in position, however ill the patient may be. Nothing should be given by the mouth, but saline solution should be injected into the rectum or subcutaneously. In severe cases a jejunostomy should be performed, the patient being fed through the stoma till the stomach contracts to its normal size.

HYPERTONUS

Ætiology.—Hypertonus is most commonly associated with very active peristalsis, rapid evacuation, and hyperchlorhydria. The condition is

congenital and often familial, and constitutes the "hypersthenic gastric diathesis" (p. 524), which is the essential predisposing cause of duodenal ulcer (p. 543).

Symptoms.—Hypertonus does not itself give rise to symptoms. If, however, an individual with the hypersthenic gastric diathesis becomes neurasthenic, or develops duodenal ulcer, some of his symptoms are caused by the hypertonus. A comparatively small quantity of food is sufficient to produce a rise in intragastric pressure, which results in a feeling of fullness, independent of the nature of the food, but varying in degree with its bulk and the rapidity with which it is eaten. The rapid evacuation of the stomach which commonly occurs when it is hypertonic gives rise to a feeling of emptiness and hunger about three hours after meals: immediate relief occurs when anything is eaten or drunk.

Diagnosis.—Hypertonus can only be diagnosed with certainty by means of the X-rays. In the erect position the stomach is diagonal (Fig. 16 (b)) or

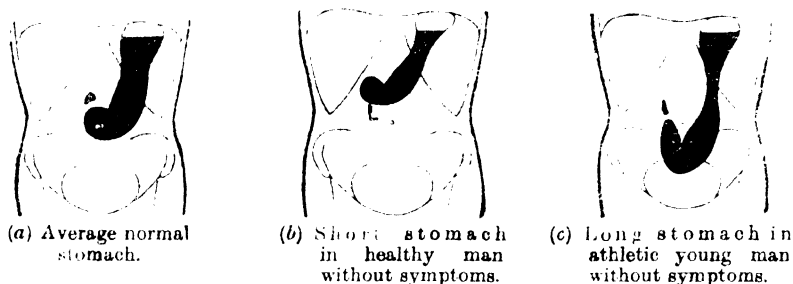

FIG. 16.—Variations in length of stomach in healthy individuals.

even horizontal, instead of almost perpendicular as in most normal subjects (Fig. 16 (a)), and the pyloric vestibule, instead of the greater curvature of the body of the stomach, is its lowest part, being situated a considerable distance above the umbilicus. Peristalsis is either normal or exaggerated, and the pylorus tends to be relaxed, so that the stomach empties itself with unusual rapidity. The only condition with which confusion may arise is a leather-bottle stomach, in which the infiltrated stomach is similar in size and shape; no peristalsis, however, is seen, the very rapid evacuation depending upon the fact that the infiltrated pylorus is dilated and incompetent.

Treatment.—Apart from the treatment of any condition with which hypertonus may be associated, it is important that regular intermediate feeds should be taken in addition to the ordinary meals, in order that the stomach should not be empty for too long a period at a time. Belladonna is the only drug which has the effect of diminishing excessive tone, but a table-spoonful of olive oil taken before meals helps to prevent the too rapid evacuation of the stomach.

SPASM: SPASMODIC HOUR-GLASS STOMACH

Ætiology.—Spasm of a narrow band of circular muscle fibres may be produced reflexly by a gastric or duodenal ulcer, chronic appendicitis, or

cholecystitis. An ulcer on the lesser curvature is the most common of the causes, the position of the spasm corresponding with that of the ulcer.

Symptoms and Diagnosis.—The spasm in the centre of the stomach leads to the production of an hour-glass stomach. There are no characteristic symptoms, but the spasm is often the only objective gastric sign which is present in the dyspepsia of chronic appendicitis and gall-stones. It is important to be able to recognise the functional nature of the condition, as many needless operations for supposed organic hour-glass stomach have been performed as a result of misinterpreting the appearance seen with the X-rays. A spasmodic stricture varies in degree during a single and at different examinations, and it never gives rise to sufficient obstruction to cause stasis for 6 hours or increased peristalsis in the proximal segment. A spasmodic stricture differs from the orthostatic stricture often seen in gastroparesis by persisting when the patient lies down, and by its disappearance on vigorous massage and sometimes after the administration of atropine.

VOMITING

Ætiology.—(a) *Central vomiting.*—Vomiting is only rarely under the control of the will. But a person who has vomited a number of times owing to some central, reflex or toxic cause, may suggest to himself that certain circumstances will invariably cause him to vomit. The hysterical vomiting which results is a common sequel of vomiting due to other causes.

Various emotions, especially those of disgust and fear, may result in vomiting, especially in individuals with an abnormally excitable nervous system. This vomiting may occur as a result of incidents which subconsciously revive the memory of an emotion which on some particular occasion caused vomiting. Thus a woman who on one occasion vomited as a result of terror in a railway carriage, subsequently vomited whenever she travelled in a train and after a time in any vehicle and even in closed places, such as a church, from which she could not readily escape. The vomiting was associated with a vague feeling of fear, but not consciously with the incident which was the primary cause.

Certain organic nervous diseases, such as cerebral tumour and meningitis, are frequently accompanied by vomiting, which may also occur in compression and in concussion caused by injury. This is due partly to increased intracranial pressure, and partly to direct irritation of higher parts of the brain, from which impulses pass to the vomiting centre. In the case of cerebral tumour the relief of intracranial pressure by trephining may, therefore, cause the vomiting to cease.

(b) *Reflex vomiting.*—Reflex stimulation of the vomiting centre is the most common cause of vomiting. The most important source is the stomach itself, irritation of the mucous membrane by abnormal constituents of the gastric contents, whether introduced in the food or resulting from bacterial decomposition, being a frequent cause. Gassing was a common cause of vomiting during the Great War, some of the irritant gas being dissolved in the saliva, which was secreted in excess and then swallowed. Over-distension with food, especially if it occurs rapidly, as when a big meal is bolted, or if it continues for an abnormally long period as a result of pyloric obstruction,

has the same effect. In all these cases more or less relief to the local symptoms results from vomiting.

Painful stimulation of any afferent nerves, but particularly of those passing from abdominal viscera, such as occurs in the attacks of pain associated with gastric ulcer, in biliary and renal colic and in intestinal obstruction and peritonitis, often causes vomiting. Tickling the fauces is a common method of inducing vomiting; vomiting may also be excited reflexly from the lungs in phthisis and from the heart when it is dilated, and the vomiting of migraine is in most cases a reflex from the eyes.

Sea-sickness is caused by a reflex arising from abnormal stimulation of the semicircular canals. The vomiting in diseases of the ear, in which the semicircular canals are directly or indirectly involved, as in Ménière's disease, is of similar origin. The vomiting of early pregnancy is probably reflex; when persistent it is, I believe, always hysterical and therefore curable by psychotherapy.

(c) *Toxic vomiting*.—Some emetics, such as apomorphine, cause vomiting by direct irritation of the vomiting centre, and this is also the cause of post-anæsthetic vomiting. Other emetics, such as warm water containing salt, and copper and zinc sulphate, act reflexly from the stomach, and are consequently only effective when they are swallowed, whilst drugs, such as tartar emetic and ipecacuanha, act in both ways.

Poisons produced in the body, as in uræmia, Graves' disease and Addison's disease, may irritate the vomiting centre. In uræmia, however, the action is partly reflex owing to the excretion into the stomach of toxins which should be excreted by the kidneys. The bacterial toxins in acute fevers, especially scarlet fever, often excite vomiting. Toxic vomiting differs from central vomiting and some cases of reflex vomiting in being almost invariably preceded by nausea.

Treatment.—The only treatment of vomiting is to remove the cause. In toxic cases, and those due to reflexes from the stomach itself, complete evacuation by the stomach tube gives relief. As purely symptomatic treatment, the most useful drugs are dilute hydrocyanic acid, 3 to 6 minims of which should be given in 1 drachm of water, and chloretone, 5 grains of which can be given in a cachet and repeated, if necessary, three or four times at intervals of 2 hours. Chloretone is particularly useful for sea-sickness. It tends to produce drowsiness and may cause considerable malaise; it is therefore unsuitable for frequent administration.

REGURGITATION

Regurgitation of small quantities of food into the pharynx and less often into the mouth without effort and without nausea occurs in various forms of dyspepsia. It is often accompanied by a scalding sensation in the pharynx. Regurgitation is frequently associated with flatulence due to aerophagy, the unsuccessful efforts made by the patient to bring up wind when no excess is present in the stomach resulting in regurgitation of some of its fluid contents. It must be distinguished from regurgitation of saliva from the œsophagus—so-called waterbrash (p. 510). No special treatment is required beyond that of the primary condition; the momentary discomfort is relieved by drinking some water or taking a little sodium bicarbonate.

RUMINATION

Synonym.—Merycism.

Ætiology.—Rumination is a very rare condition, which may occur in several members of the same family. It occasionally develops as a result of imitation, and is most frequent in neurotic individuals, in epileptics and in the insane. It generally begins between the ages of 12 and 20.

Symptoms.—Rumination consists in the return into the mouth of successive portions of a considerable part of the gastric contents after the completion of a meal. The food is chewed again and then swallowed; the process is not at all distasteful and appears quite natural to the patient. This serves to distinguish rumination from regurgitation; moreover, it is never associated with dyspepsia.

Treatment.—In some cases suppression of rumination makes the patient feel unwell. When this is not the case, an attempt should be made to control it by an effort of will. Food should be eaten slowly, and fluids taken as much as possible apart from meals.

SECRETORY DISORDERS

I. HYPERCHLORHYDRIA AND HYPERSECRETION

(a) *Physiological hyperchlorhydria: the hypersthenic gastric diathesis.*—If the results obtained with a fractional test-meal in 100 normal individuals are plotted, the 80 showing the greatest resemblance to each other may be taken to represent the "average normal," as shown by the shaded area in the diagrams (Bennett and Ryle, pp. 528 and 547). Of the 100 individuals, 8 showed such an excess of the average normal that they can be regarded as having hyperchlorhydria. The majority of healthy individuals with hyperchlorhydria have also hypertonus (p. 520), the continued condition being known as the hypersthenic gastric diathesis. This does not in itself give rise to symptoms, but is an essential predisposing cause of duodenal ulcer (p. 542), and when an individual with the diathesis happens to become neurasthenic, his symptoms assume a special form which is the result of the unusually active motor and secretory functions of his stomach.

(b) *Reflex hyperchlorhydria.*—Whereas hyperchlorhydria is only present in about 10 per cent. of normal individuals, it is found in about 55 per cent. of patients with chronic appendicitis and 20 per cent. of those with cholecystitis, with or without gall-stones. It is probable, therefore, that chronic inflammation of the appendix and the gall-bladder leads reflexly to hyperchlorhydria. Reflex hyperchlorhydria may sometimes occur in gastric ulcer, but the hyperchlorhydria of duodenal ulcer precedes its development, and is just as marked after the ulcer has healed as when it is in the height of its activity, so that it is almost certainly a cause rather than a result of the ulcer.

(c) *Toxic hyperchlorhydria.*—Excessive smoking increases the secretion of hydrochloric acid, especially in individuals in whom the secretion is already above the average. Consequently smoking is often an accessory factor in the development of duodenal ulcer. Experimentally pilocarpine has been shown to stimulate the secretion of gastric juice.

Symptoms and Treatment.—Hyperchlorhydria does not itself give rise to symptoms and therefore, if accidentally discovered, it requires no treatment. Its presence in duodenal ulcer, in some cases of chronic appendicitis and chronic cholecystitis, and in some cases of neurasthenic dyspepsia, is responsible for certain symptoms present in these conditions, and in the treatment of these conditions a diet is selected which produces a minimal secretion, and drugs are given which inhibit secretion or neutralise some of the acid present. It is, however, more rational to discuss the symptoms and treatment of the individual diseases rather than those of the hyperchlorhydria, which is only one feature in them and which does not give rise to symptoms or call for treatment when present alone.

(d) *Hypersecretion.*—When a gastric or duodenal ulcer is situated sufficiently near the pylorus to interfere either directly or reflexly with its normal functions delay in evacuation occurs. Consequently the stimulation to gastric secretion is prolonged, and the curve obtained with a fractional test-meal has a characteristic “climbing” character. When the obstruction is insufficient to cause a twelve-hour stasis of food, the difficulty in evacuation may still lead to the accumulation of a large volume of acid juice in the morning, which is evacuated when the tube is passed in the fasting patient before the test-meal is given. Paroxysmal hypersecretion is present in one form of tabetic gastric crisis.

II. ACHYLIA GASTRICA, ACHLORHYDRIA AND HYPOCHLORHYDRIA

By *achylia gastrica* is meant the complete absence of secretion of hydrochloric acid by the stomach; strictly speaking it should also mean that no pepsin is secreted, but in most cases a small quantity is found in the gastric contents. By *achlorhydria* is meant the absence of free hydrochloric acid from the stomach throughout a fractional test-meal. This may be due to *achylia gastrica*, or to the presence of excess of the alkaline secretion of the pyloric vestibule or of regurgitated duodenal contents leading to the complete neutralisation of the free acid, whether this is secreted in normal or diminished quantity. The two conditions can be distinguished by estimating the quantity of combined hydrochloric acid in the one-hour fraction of the test-meal; this is more or less greatly increased if *achlorhydria* is due to neutralisation of the acid by excess of alkaline fluids. *Achlorhydria* is also caused by the presence of excess of mucus in the gastric contents; if the test-meal is repeated after washing the stomach out, free acid is found to be present, often in normal amount.

Hypochlorhydria is the condition in which free hydrochloric acid is still present in one or more fractions of a test-meal, but the curve obtained is lower than the lower limit of the variations present in 80 per cent. of normal individuals.

Ætiology.—(a) *Achylia Gastrica.*—(i) A large majority of cases of *achylia gastrica* are congenital and constitutional. It may occur in infants and is present in about 1 per cent. of normal young adults. It is often familial, being present in several members of a family in one or more generations. It may be regarded as an inborn error of function, as it is not associated with any recognisable changes in the gastric mucous membrane, though secondary

gastritis may result from the lack of the normal diluting and antiseptic properties of the gastric juice.

(ii) *Achylia gastrica*, as distinct from the achlorhydria caused by the presence of excess of mucus, is a rare sequel of prolonged and severe chronic gastritis, in which atrophy of the mucous membrane eventually occurs. It occurs as a temporary result of acute gastritis; secretion rapidly becomes normal again except in the severe toxic cases, in which the mucous membrane is more or less destroyed by the irritant. If the patient survives, permanent achylia is present.

(iii) In rare cases the complete inhibition of secretion, which is produced by fear and other depressing emotions, remains after the cause has apparently disappeared, but in all probability the mental disturbance is still present though in a less obvious form.

(b) *Achlorhydria*.—(i) The most important cause of achlorhydria is cancer of the stomach. It is present in about 60 per cent. of cases, and is due partly to excess of blood and other alkaline secretions from the surface of the growth, but mainly to the associated chronic gastritis (*vide* p. 540). Achlorhydria is also common in syphilis of the stomach.

(ii) Achlorhydria is often present in chronic gastritis. In these cases it is a result of neutralisation with excess of mucus, and of obstruction to the mouths of the ducts by adherent mucus.

(iii) After a gastro-enterostomy the entrance of the alkaline duodenal contents from the proximal limb of the jejunum and the rapid escape of acid through the distal limb lead to complete achlorhydria in the majority of cases, unless the operation was performed for duodenal ulcer: as the hyperchlorhydria associated with that condition is a cause and not a result of the ulcer, the large quantity of acid still secreted is sufficient to prevent complete neutralisation and the production of achlorhydria.

(c) *Hypochlorhydria*.—All conditions leading to achlorhydria, except of course constitutional achylia, may also cause hypochlorhydria. It is also sometimes present in neurasthenia and chronic infections, such as tuberculosis, owing to the absence of appetite, which normally calls forth the initial secretion of gastric juice at the beginning of a meal, together with actual inhibition of secretion caused by repugnance for food.

Symptoms and Diagnosis.—When the deficient secretion of gastric juice is secondary, the symptoms to which it gives rise are to a great extent obscured by those of the primary condition. No doubt some of the symptoms of gastritis and cancer of the stomach are a result of the hyposecretion which is present, as the administration of hydrochloric acid often improves the digestion in such cases. The same is true with regard to the indigestion of neurasthenia in which hyposecretion is found. The part taken by hyposecretion in the production of the symptoms in these conditions can best be judged from a consideration of constitutional achylia gastrica, all the symptoms of which are due to the deficient secretion of gastric juice.

Constitutional achylia gastrica may be completely latent and discovered accidentally. There may be a history dating from childhood of repeated attacks of diarrhoea, of abdominal discomfort with anorexia, and nausea. In adult life these attacks tend to become more frequent and severe. They are generally brought on by a hurried meal or by an unusually large or

indigestible one. In the intervals between the attacks the patient is often not completely comfortable, and there is sometimes a permanent distaste for meat, which also tends to upset the patient more than any other food. The discomfort comes on immediately after meals and lasts for an hour or two, the duration depending upon the amount of food taken. Though nausea is common, there is generally no vomiting. Flushing of the face during meals and even permanent rosacea are often caused by achylia gastrica.

In many cases chronic diarrhoea is present, either alone or associated with the gastric symptoms just described.

In uncomplicated cases there is no tenderness and nothing abnormal is found on physical examination. The X-rays sometimes show that the stomach is short and high and empties itself with extreme rapidity owing to the relaxed condition of the pyloric sphincter. Owing to this the patient may complain of a sinking feeling about 3 hours after meals, which is at once relieved by taking more food.

A test-meal shows that the gastric contents are small in bulk, viscid, neutral or alkaline in reaction, and contain no free hydrochloric acid. Before accepting a diagnosis of achlorhydria the test-meal should be repeated after washing out the stomach. In very rare cases the psychological effect of the passage of the tube inhibits the secretion of gastric juice on the first occasion, but this never occurs a second time. More frequently the excessive quantity of alkaline saliva swallowed when the tube is passed neutralises any free acid which is present in cases in which the latter is deficient though not really absent. This, again, does not occur when the meal is repeated. In almost all cases of chronic gastritis, whether due to alcohol or not, in which achlorhydria is found, this is due to the neutralisation by alkaline mucus of the acid which is still secreted, though perhaps in diminished quantity; when therefore the meal is repeated after washing away the alkaline mucous fluid present in the fasting stomach, achlorhydria is found to be no longer present. Very rarely in cancer a small quantity of free acid is found to be still present if the meal is repeated after washing out the stomach.

Diagnosis.—Before accepting a diagnosis of constitutional achylia the possibility of cancer, atrophic gastritis, or much more rarely of syphilis must be considered. In many cases there is nothing in the history of the symptoms to suggest the presence of any of them, and achylia is quite frequently discovered in the course of a routine examination of a patient suffering from one of the diseases of which it is an important predisposing factor. The diagnosis from atrophic gastritis is impossible, except in some cases from the history, as constitutional achylia is frequently complicated by the presence of secondary gastritis, so that excess of mucus is produced. If the gastric contents contain blood obvious to the naked eye, cancer is probably present; occult blood should be looked for in the stools, as it is generally found in cancer of the stomach even when it is absent from the gastric contents, and it is rare in constitutional achylia, though it may be present with severe chronic gastritis.

If the X-rays show that the stomach is small and empties itself with abnormal rapidity, either constitutional achylia or the leather-bottle type of gastric carcinoma is present; in the latter the outline of the stomach may be irregular, and peristalsis is weak or even absent, the rapid evacuation being due to pyloric incompetence from a rigid and dilated sphincter. In all cases of cancer, except the leather-bottle type, the stomach is normal in size or

dilated, evacuation is often delayed, and in most cases some irregularity in the outline can be recognised.

COMPLICATIONS.—Addison's (pernicious) anæmia and subacute combined degeneration of the spinal cord are invariably associated with complete achlorhydria, which is due to constitutional achylia in the large majority of cases (Fig. 17), but in a small minority to chronic gastritis, gastro-enterostomy, complete gastrectomy, and cancer of the stomach. The achlorhydria is the primary condition; there is consequently often a history of chronic diarrhoea or other symptoms to which it has given rise, dating for months or years before the onset of anæmic or nervous symptoms, and in several cases the existence of achylia has actually been known during this time. The achlorhydria allows the duodenum to become infected with streptococci from the mouth and the increased alkalinity of the contents of the small intestines leads to their invasion with *B. coli* from the colon. The hæmolytic poisons produced in the intestines give rise on absorption to the destruction of the blood and changes in the bone marrow, and the neurotoxic poison

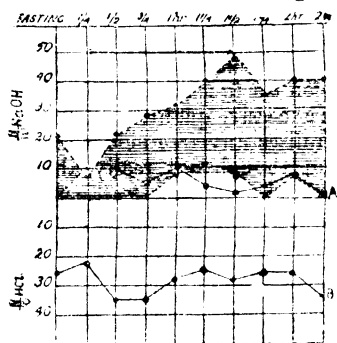

FIG. 17.—Fractional test-meal in case of Addison's anæmia. A, total acidity; B, amount of N/10 HCl required to produce free acid; shaded area represents the limit of free HCl in 80 per cent. of normal individuals.

fact that achlorhydria or hypochlorhydria is present in over 30 per cent. of cases of rheumatoid arthritis.

Treatment.—The food should be chewed until it is quite fluid. All raw vegetables, such as salads and pickles, and other food which cannot be chewed to a fluid consistence must be avoided. Very little meat should be eaten, and neither game nor ripe cheese allowed. Plenty of cream and butter should be given. If chronic gastritis, whether primary or secondary to the achylia, is present, the diet should at first be much more strict.

The only drug of real value is hydrochloric acid, but if hyposecretion and not complete achylia is present, a bitter mixture containing sodium bicarbonate taken before meals may stimulate secretion. Large quantities of hydrochloric acid should be given, and the treatment continued for the rest of the patient's life in all cases of constitutional achylia. Small quantities of acid are required as symptomatic treatment for the hypochlorhydria

gives rise to the degeneration of the spinal cord. The frequent occurrence of Addison's anæmia and subacute degeneration of the cord in more than one member of a family is due to the familial occurrence of achylia gastrica. A complete blood examination should be made in every case of achylia, even if the patient is not pale and has no symptoms of anæmia, as by this means Addison's anæmia has in rare instances been diagnosed at a very early stage when the hæmoglobin percentage was 70 or more. The presence of achlorhydria permits the intestines to be infected with abnormal case. A secondary ascending infection explains the frequency of achlorhydria in chronic cholecystitis and gall-stones (40 per cent.), and chronic appendicitis (33 per cent.). A streptococcal infection of the bowel secondary to achlorhydria also accounts for the

of neurasthenia, chronic infections, chronic gastritis with true achlorhydria and cancer. In chronic gastritis the secretion of gastric juice sometimes returns when the condition improves; test-meals should therefore be given from time to time to see whether it is necessary to continue the administration of the acid.

In Addison's anæmia and subacute combined degeneration of the cord, in which it is important to replace the absent acid as completely as possible, as much as 2 drachms of dilute hydrochloric acid (B.P.) should be given in 10 to 15 ounces of water three times a day. The first doses should be taken fasting, one hour before breakfast, when no food is present in the stomach to neutralise any of the acid; the second and third doses should be taken with lunch and dinner. With the addition of sugar and orange or lemon-juice the acid solution is a quite agreeable beverage. Pepsin (5 gr.) may be added in powder form to the acid taken at meals, though it is very rarely absent, and often not greatly diminished in quantity even in complete achylia gastrica. When the achylia is not associated with any serious disease 1 drachm of dilute acid 3 times a day is generally sufficient, and in some cases 30 or 40 minims may be enough to control such symptoms as diarrhœa.

SENSORY DISORDERS

ANOREXIA

Definition. Loss of appetite.

Anorexia occurs in chronic gastritis and cancer of the stomach, and in toxicæmic conditions, such as acute fevers, tuberculosis and cancer. It is often present when for any reason the tongue is dry or furred. It is an extremely common symptom in neurasthenia, in which it is due in part to the depressed condition of the nervous system and in part to dietetic restrictions, often made by the patient himself with the object of relieving his dyspepsia. Neurotic girls sometimes take too little to eat for fear of becoming fat. In all such cases the diminution in the quantity of food eaten leads to a corresponding diminution in the appetite, until in severe cases the condition known as *anorexia nervosa* finally develops, the patient taking little or no food and becoming excessively emaciated. This is really a form of *hysterical anorexia*, which may also result from the perpetuation of the loss of appetite which may temporarily follow severe emotional disturbance. In other cases it is associated with *psychasthenia*; the initial refusal of food is caused by some phobia or obsession, and the complete loss of appetite which follows is perpetuated as an hysterical symptom.

Treatment.—The anorexia of neurasthenia can only be overcome by persuading the patient to eat more. This is often very difficult and requires considerable tact. A strong-willed nurse is a great help, and food should be given at short intervals throughout the day. As soon as the patient begins to eat an increased quantity, the appetite returns. In severe cases of hysterical anorexia complete isolation is essential, together with vigorous psychotherapy in the form of explanation of the psychological origin of the anorexia, persuasion to eat and re-education of the appetite.

NAUSEA

Ætiology.—Nausea most commonly precedes vomiting, and is relieved when the stomach is emptied. It may, however, occur as an independent symptom, particularly in women; the majority of such cases occur in chlorotic girls or at the climacteric. Although the significance of the symptom is not clear, it must be regarded in these cases as of nervous origin; probably it is often hysterical and due to the perpetuation by auto-suggestion of nausea, which originally resulted from the emotion of disgust, although the actual exciting incident may have been forgotten. Nausea may be the only symptom in achylia gastrica, chronic gastritis, or even in the earliest stage of carcinoma of the stomach; it may be the chief complaint in chronic appendicitis, cholecystitis, and infection of the intestines with worms. It is occasionally the most prominent symptom in early tuberculosis and in the commencement of pregnancy. All these possibilities should be excluded before regarding it as of nervous origin. The urine should be carefully examined, as nausea is occasionally an early symptom of nephritis and of infection of the urinary tract, and in men it may result from prostatic disease.

Symptoms.—The nausea may be constant or periodic; it is often quite independent of the kind or nature of the food taken. The patient may wake up with severe nausea, which makes it difficult for him to take any food during the day. Moreover, he often thinks the symptom is due to gastric disease, and he consequently reduces the amount of food he takes; severe loss of weight may result. The nausea is often increased by emotional disturbances, and may be less troublesome when the mind is fully occupied.

Treatment.—If all organic causes can be excluded, the only effective treatment is to remove the patient from his home surroundings and insist upon a proper quantity of food being taken. An attempt should be made to find the emotional disturbance which may have been the exciting cause of the symptom, as a convincing explanation of this is likely to lead to the disappearance of the nausea.

GASTRIC FLATULENCE; AEROPHAGY

Flatulence, or the presence of excess of gas, may occur simultaneously in the stomach and the intestine, but in many cases it is confined to the stomach and less frequently to some part of the intestines.

Ætiology.—In each case flatulence may be due to (a) excessive production of gas by fermentation or putrefaction. (b) the introduction of excess of air by aerophagy, or (c) deficient elimination.

(a) Fermentation in the stomach is never sufficiently excessive to give rise to flatulence unless pyloric obstruction is present. Deficient hydrochloric acid does not itself result in increased bacterial activity in the stomach; thus flatulence is not a symptom of achylia gastrica, in which the rate of evacuation is often increased. But the type of fermentation depends upon the quantity of hydrochloric acid present; in non-malignant pyloric obstruction, especially if it is due to an active ulcer, hypersecretion is present.

and acetic acid fermentation occurs, with abundant production of carbon dioxide, whereas in cancerous obstruction, in which the secretion of gastric juice is deficient, butyric and lactic acid fermentation, sometimes associated with the putrefaction of proteins, occurs, and much less gas is evolved. In the former case the gas is odourless; in the latter offensive.

(b) **Aerophagy** is the commonest cause of flatulence. It is generally associated with nervous dyspepsia, but it also occurs with organic diseases, such as gastric and duodenal ulcer and cholecystitis, and the pain in angina pectoris frequently causes aerophagy. The patient feels some slight discomfort in the stomach, which he thinks is due to "wind" and which he imagines he can "disperse" by eructation; as there is really no excess of gas present, the attempt proves unsuccessful, but results in the swallowing of air. After half a dozen or more attempts have been made without success, air being swallowed on each occasion, the stomach becomes so distended with air that an attempt is at last successful. The excessive salivation, which often occurs in gastric disorders associated with hyperchlorhydria and in septic conditions of the mouth and naso-pharynx, also leads to flatulence, as air is swallowed with each mouthful of saliva. The severest cases of aerophagy occur independently of dyspepsia in women who are intensely neurotic; the symptom is then hysterical. A little saliva with a large quantity of air is swallowed until the stomach is distended, when it is noisily pumped backwards and forwards between the stomach and œsophagus by spasmodic movements of the diaphragm, and periodically expelled with a loud report.

(c) **Deficient elimination of gas** occurs when absorption is diminished owing to catarrh or to the obstruction of the portal circulation which occurs in cirrhosis of the liver and heart failure; swallowed air and the gases produced by fermentation are insufficiently absorbed, and severe flatulence results.

Symptoms.—The most common symptom resulting from gastric flatulence is a sensation of fullness in the upper part of the abdomen, especially under the left costal margin. The abnormal accumulation of gas in the stomach pushes up the diaphragm; this may cause palpitation and pseudo-anginal attacks. Dyspnoea results in individuals who are predisposed by such conditions as asthma and cardiac weakness, and flatulence may also be the immediate cause of an attack of true angina pectoris, though more frequently the angina gives rise to aerophagy.

Diagnosis.—When a patient complains of "flatulence" it is first necessary to ascertain whether excess of gas is really present. This can be done most readily and accurately by means of the X-rays, as it is often difficult to distinguish by percussion whether an accumulation of gas is in the stomach or in the splenic flexure of the colon.

Pseudo-flatulence may be due in neurotic individuals to spasm of the diaphragm: a sensation of great distension is suddenly experienced, and the abdomen becomes so enlarged that the clothes have to be loosened. The distension disappears as suddenly as it came, without eructation or passage of flatus; it also disappears under an anæsthetic and on firmly compressing the whole of the abdomen for some minutes. The absence of excess of gas in the stomach can at once be detected with the X-rays, which also show the low position of the diaphragm and the absence of respiratory movements. The condition can be cured by teaching the patient to breathe properly with his diaphragm.

Pseudo-flatulence is more often due to the patient misinterpreting the sensation of fullness which is caused by the increased intragastric pressure produced by sudden distension of the stomach, especially if it is of the hypertonic form, with excess of food and drink which have been too rapidly consumed. There is no abdominal swelling or increase in gastric resonance, and the patient is unable to bring up any gas, but the condition is often complicated by aerophagy.

The gas brought up in cases of aerophagy is odourless and tasteless; when caused by putrefaction in malignant pyloric obstruction it is offensive, and this may occasionally be the first symptom of a growth. Aerophagy is probably present if eructation is frequently repeated; the diagnosis is certain if it occurs six or more times in rapid succession, as fermentation cannot give rise to such a large quantity of gas. Eructation occurring before breakfast in the absence of pyloric obstruction is always due to aerophagy, as there is nothing in the stomach from which gas could be produced. The diagnosis can be confirmed by means of the X-rays, with which it is easy to watch the whole process of aerophagy.

Treatment.—The treatment of flatulence due to excessive fermentation consists in removing the cause. When flatulence is due to aerophagy, it is generally only necessary to explain to the patient the cause of his trouble in order to cure him. He should be told not to eructate, however much he may desire to do so. If he finds it very difficult to restrain himself, he should open his mouth or clench his teeth upon a cork, whenever the desire is very strong, as it is then difficult to swallow air, though any excess of gas in the stomach can be expelled. When aerophagy is due to dyspepsia, this requires appropriate treatment. Momentary relief, sufficient to help the patient to forgo eructation, can generally be obtained by sipping hot water or chloroform water, or by taking a few drops of a carminative, such as oil of cinnamon or peppermint, on a lump of sugar, but the use of spirits for this purpose should be prohibited.

In severe cases of hysterical aerophagy, isolation is required. A stomach-tube can be passed periodically and kept in the stomach for some minutes, the patient having previously been told that the treatment will give her permanent relief; but with intelligent patients simple explanation and persuasion are equally effective and more satisfactory than gross suggestion of this kind, as there is much less liability to relapse.

GASTRIC SYMPTOMS OF FUNCTIONAL NERVOUS DISORDERS

NEURASTHENIC OR NERVOUS DYSPEPSIA

Ætiology.—Most neurasthenic patients suffer from indigestion, partly as a result of their abnormally irritable nervous system and partly as a result of depressing emotions, mental and physical overwork, and the other factors concerned in the production of neurasthenia, as these tend in themselves to inhibit the motor and secretory functions of the stomach.

Symptoms.—The gastric symptoms in neurasthenia are characterised by their extreme irregularity, the patient feeling very ill one day and quite

well the next without any obvious reason for the change. The most constant complaint is of vague abdominal discomfort, which rarely amounts to actual pain. It is generally worst in the morning and improves towards evening, but in some cases the symptoms increase when the patient becomes more fatigued towards evening. The discomfort is worse after meals, a sensation of fullness being felt as soon as a small quantity of food has been eaten, but it may be present to a less extent before breakfast. It has little relation to the amount or the kind of food, differing in that way from the discomfort of organic gastric disorders; it is increased by worry or excitement, while some new interest, whether it be a change of surroundings, a game, a conversation, or a new medicine, leads to its temporary disappearance. Nausea sometimes occurs, but vomiting is unusual. Most patients complain of flatulence, which is more commonly due to aerophagy than to excessive fermentation, but may be nothing more than the result of misinterpreting the sensation of fullness, no excess of gas being present (see Flatulence, p. 530). The appetite is always diminished, though it varies considerably from day to day (see Anorexia, p. 529). As insufficient food is taken, the nervous system becomes more depressed; this reacts again on the digestion, a vicious circle being produced.

Examination of the stomach may show that atonic dilatation (p. 519) is present. The secretion of gastric juice may be diminished as a result of the neurasthenia. If neurasthenia develops in a patient with the hypersthenic gastric diathesis, the symptoms are likely to be those of hypertonus (p. 520) and hyperchlorhydria (p. 521). Constipation is almost constantly present. The abdominal muscles may be tense, so that examination may be difficult, but there is never any great degree of tenderness, and what is present is diffuse and variable in position rather than localised and constant. In other cases the abdominal muscles are weak, and symptoms due to visceroptosis may be present in addition to those of uncomplicated neurasthenic dyspepsia.

The gastric symptoms are always associated with other symptoms of neurasthenia, such as headache, backache and insomnia, and the anorexia leads to progressive loss of weight and strength. The abdominal discomfort may be accompanied by flushing of the face, palpitation and coldness of the extremities. The patient is generally depressed and pessimistic; he pays great attention to all his bodily functions, constantly looking at his tongue, taking his temperature and examining his faeces. His account of his symptoms is full of details, and he often has some theory to account for them, believing himself to be suffering from "acidity," "uric acid," or "liver," or fearing that he is afflicted with cancer.

Treatment.—The patient's confidence can only be gained after a very thorough examination. He can then be told that he has no organic disease, and that with perseverance he will get well. The general neurasthenic condition first requires attention; for this mental and physical rest, followed by graduated exercise, and sufficient food to overcome the inanition, which is generally present, are the chief indications. Pleasant surroundings, cheerful companions and appetising food are of great importance, and consequently strict isolation is not required. The treatment of the stomach itself depends upon the condition of the motor and secretory functions, and has already been described.

HYSTERICAL DYSPEPSIA

Ætiology.—When symptoms, such as anorexia, nausea, vomiting, and abdominal pain, have been caused by emotional disturbance, or by gastritis, gastric ulcer, chlorotic dyspepsia, appendicitis, or other organic cause, they may continue or recur as the result of suggestion after the original cause has disappeared. They are then hysterical symptoms.

Symptoms.—Hysterical vomiting occurs during or immediately after meals; it is effortless and generally unaccompanied by nausea, so that a patient may vomit the meat and vegetables and immediately afterwards be ready to eat the sweets, which he may manage to retain. The stomach is generally only partially emptied, so that nutrition is preserved, but in rare cases nothing is retained, and severe emaciation, together with the changes in the urine which result from starvation and have erroneously been ascribed to acid intoxication, result. The diet has often no effect, vomiting being as frequent with milk alone as with a full diet.

When the vomiting of early pregnancy, which is probably reflex in origin, occurs after every meal instead of only in the morning, and when it persists after the eighth week, it is often called the "pernicious vomiting of pregnancy." It has generally been regarded as toxic on account of certain changes in the urine and associated symptoms. I am convinced, however, that it is always hysterical, as in my experience it can invariably be cured by psychotherapy with great rapidity. The changes in the urine—excess of organic acids and a rise in the ammonia index (the proportion of nitrogen present as ammonia compared with that as urea) are entirely secondary to the starvation and dehydration which result from persistent vomiting. However marked these changes may become—and I have known the ammonia index rise from the normal 5 to 28—and however severe the so-called toxic symptoms may be, such as dry, black tongue, and a pulse as rapid as 160, these all disappear within 24 or 48 hours with psychotherapy in the form of explanation and persuasion, without either suggestion or any drug treatment. The condition must of course be distinguished from the vomiting which begins in the later stages of pregnancy and is only one symptom of some obviously toxic condition such as eclampsia or acute yellow atrophy of the liver.

Hysterical gastralgia is a not uncommon symptom in girls who have previously suffered from genuine gastric pain as a result of chlorosis or gastric ulcer. It is very irregular in its relations to the time and character of meals; it may occur before as well as after breakfast, and may be absent after a very indigestible meal, during which the patient has had her mind distracted. It is accompanied by very diffuse deep tenderness, which may be associated with a large area of cutaneous hyperaesthesia, probably always produced by suggestion on the part of the observer, as its situation and extent can be easily varied from day to day by suggestion. The gastralgia may be associated with vomiting, which does not always relieve it.

Treatment.—A patient with hysterical vomiting should be kept in bed and isolated. After the primary cause has been discovered and explained to the patient, he should be made to realise that now that this has disappeared, his stomach has simply developed a bad habit, which it must be educated to

give up. In the large majority of cases complete recovery rapidly ensues. If, however, improvement is slow, the patient should be given an additional helping of any food he vomits, even if this has to be repeated two or three times. In hysterical gastralgia, rest in bed, isolation, full diet and psychotherapeutic conversations generally effect a rapid cure. (See also Aerophagy, Anorexia and Nausea.)

MIGRAINE AND GASTRIC CRISES OF TABES

For the Gastric Symptoms of Migraine, see p. 1548; and for the Gastric Crises of Tabes, see p. 1500.

ANÆMIC DYSPEPSIA

Ætiology.—Anæmic dyspepsia is very common between the ages of 15 and 30. Though much more frequent among females, exactly the same condition may occur in males. It is in part due to improper food, and it occurs especially among girls of the poorer classes, whose diet consists largely of bread and butter and tea, with little or no meat or green vegetables. I do not regard the so-called chlorotic blood-picture as a necessary factor, as I am convinced that it is no more a constant sign of the condition known as chlorosis than the dilated heart or digestive symptoms: two patients may complain of exactly the same symptoms and both get rapidly well with the same treatment, although one has typically "chlorotic blood" and the other has perfectly normal blood. Severe cases of anæmic dyspepsia have, however, become less common during the last fifteen years, corresponding with the almost complete disappearance of severe chlorosis.

Pathology.—The gastric symptoms in chlorosis are mainly due to the irritable condition of the central nervous system. Digestive processes which would normally be unfelt are consequently perceived.

Symptoms.—Almost all chlorotic patients suffer from gastric symptoms. In slight cases an uncomfortable sensation of fullness is felt high in the epigastrium immediately after meals. In severer cases, in which the digestive symptoms are the most prominent, the discomfort is replaced by actual pain. This is often followed by vomiting of a portion of each meal, with some relief to the pain. Nausea is either absent or slight, and the appetite is often unaffected, though the patient generally limits the amount of food she eats in an unsuccessful attempt to diminish the pain. The pain and sickness are quite independent of the amount and nature of the food, fluids producing as much discomfort as solid food. The symptoms are aggravated by exercise, and violent exertion may give rise to pain and sickness, even if no food has been taken for some hours. The pain is partially relieved by lying down and rest in bed prevents the occurrence of pain and sickness. Constipation is invariably present, and its relief produces some temporary improvement in the gastric symptoms.

Deep tenderness is well marked but diffuse, extending over the whole of the upper part of the abdomen. A large area of cutaneous hyperæsthesia, which is most marked or confined to the left side, is often found; but as many of these patients are highly suggestible, I am inclined to think that

this is invariably hysterical, being unconsciously suggested by the observer. Rigidity of the rectus muscles is either absent or slight in comparison with the degree of pain; it tends to disappear if the patient's attention is distracted during the examination.

The heart may be more or less dilated as a result of the chlorosis, but when the digestive symptoms are well marked, the circulatory and other symptoms of chlorosis are generally less obvious.

Chlorotic dyspepsia is sometimes associated with acute gastric ulcer; most of the symptoms which are commonly ascribed to acute gastric ulcer are due to the associated anæmic dyspepsia, with the exception of hæmatemesis, which never occurs in uncomplicated chlorosis.

Diagnosis.—Gastric symptoms in a young woman are more likely to be due to chlorosis than gastric ulcer, unless hæmatemesis occurs, in which case an acute or much less probably a chronic ulcer must be present. Chlorotic dyspepsia also differs from gastric ulcer, with which it was formerly very often confused, in the absence of any relation between the severity of symptoms and the nature and quantity of the food, and in the marked influence of exercise, which may even produce symptoms when the stomach is almost empty. Rigidity is generally more marked and tenderness more localised in gastric ulcer than in chlorosis, especially if the examination is made when the pain is at its height.

Early phthisis may give rise to almost identical symptoms, so that the chest should always be carefully examined, even if there is no other symptom pointing to pulmonary disease.

The severe pain and sickness which sometimes occur in chlorosis may lead to the idea that appendicitis is present. But the temperature never rises even a fraction of a degree; there is no local tenderness in the right iliac fossa, if care is taken to avoid suggestion, and Bastedo's inflation sign (see p. 614) is always negative.

The characteristic blood-picture is an important aid in diagnosis when it is present, but its absence is of small importance.

Treatment.—The first essential is that the patient should stay in bed until at least a fortnight after all digestive symptoms have disappeared.

However severe the pain and vomiting have been, the patient should be given a full diet at once. Even if she has been having nothing but milk for months, the combination of rest in bed and a full diet frequently causes the pain and vomiting to disappear within 2 or 3 days and sometimes even on the first day. Very rarely is it necessary to give only soft food for the first few days, but even in the worst cases the patient should be taking three good meals a day before the first week is over. It is advisable to explain to the patient that her stomach is quite capable of digesting all kinds of food, if she stays in bed and takes the medicine which will be given her: if she has already had dietetic and other treatment, it can be added that this has prepared the stomach for the greater demands which are now to be made upon it.

Twenty grains of iron and ammonium citrate with 3 minims of liquor arsenicalis and sufficient sodium sulphate to keep the bowels regular should be given in a mixture three times a day after meals, or an iron and arsenic preparation may be injected subcutaneously on alternate days.

ORGANIC DISEASES OF THE STOMACH

HÆMATEMESIS

Ætiology.—Hæmatemesis results most frequently from gastric and duodenal ulcer. It occurs, generally in smaller quantities, in cancer of the stomach. The term *gastrostaxis* was applied to the hæmorrhage which was supposed to occur, especially in chlorotic girls, in the absence of any organic lesion; but it is probable that very small, rapidly healing and often multiple acute ulcers, which readily escape detection both at operation and post-mortem, are present in such cases (see Acute Ulcer). Sometimes the mucous membrane appears at operation to “weep” blood, and the slightest touch causes hæmorrhage; this condition is generally due to hæmorrhagic gastritis resulting from some infection or intoxication, such as chronic appendicitis. There is no evidence that vicarious menstruation from the stomach ever occurs, although hæmatemesis is rather more common during menstruation than in the intervals. Hæmatemesis may result from congestion of the mucous membrane in cirrhosis of the liver and rarely in heart failure, and bleeding from the stomach is a common symptom of splenic anæmia. It may also occur in the hæmorrhagic diathesis; it is then generally preceded and accompanied by purpura and often by hæmorrhages from the nose, kidneys or other organs, but in some cases it may be the sole manifestation of the condition. Finally, blood from the naso-pharynx, mouth, œsophagus and lungs may be swallowed and vomited.

Diagnosis.—The possibility of malingering should be considered in hysterical girls if nocturnal hæmatemesis occurs during menstruation; the absence of blood from the fæces would confirm such a suspicion. Direct examination of the nose, gums and pharynx excludes the possibility of the blood coming from these sources. Hæmatemesis may be distinguished from hæmoptysis by the fact that in the former the blood is generally dark, partly coagulated and mixed with more or less food, whereas in the latter it is bright red, frothy and unclotted; in the former the symptoms may point to gastric disease, in the latter to disease of the lungs or the heart; in the former the presence of occult blood in the stools and sometimes mælena is a constant sequel and the hæmorrhage is not often repeated, whereas in the latter the stools contain no blood and the patient generally continues to expectorate blood-tinged sputum for several days. In chronic ulcer and carcinoma of the stomach a history of other gastric symptoms can always be obtained. In cirrhosis of the liver symptoms of chronic gastritis are present and the liver is generally hard and enlarged. When hæmatemesis occurs without other symptoms an acute ulcer is generally present, if splenic anæmia can be excluded by the absence of splenomegaly and leucopenia. The number of blood-platelets should also be estimated, as if they are deficient the diagnosis of the hæmorrhagic diathesis should be considered, even if no hæmorrhages have occurred in other situations.

Treatment.—The patient should be kept in the supine position, and should not leave his bed even to micturate or defecate until there has been no hæmorrhage for 48 hours. In order to keep him completely at rest

it is generally advisable to inject morphine. An alkaline powder, consisting of equal quantities of the tribasic phosphates of magnesium and calcium, should be given at frequent intervals in order to neutralise any gastric juice, which otherwise digests the clot directly it forms over the bleeding point. Nothing else should be given by mouth for 12 hours; small quantities of dilute citrated milk may then be drunk, as described in the treatment of gastric ulcer, but if hæmorrhage recurs starvation should be continued for 3 days and saline solution administered by rectum. No addition should be made to the milk diet until at least 48 hours after the disappearance of occult blood from the stools. An enema should be given the third day after the hæmorrhage if the bowels have not been opened.

If the hæmorrhage is gastric and not duodenal in origin and continues to a dangerous extent, a stomach tube attached to Senoran's evacuator should be passed; the stomach is emptied and then washed with successive half-pints of iced water until the latter is no longer tinged with blood, when a drachm of adrenalin chloride (1 in 1000) may be left in the stomach with as little water as possible. If the hæmoglobin falls below 40 per cent., the patient should be transfused.

ACUTE GASTRITIS

(a) ACUTE CATARRHAL GASTRITIS

Ætiology.—Acute catarrhal gastritis is caused by chemical irritation of the mucous membrane of the stomach. A large and indigestible meal, especially if the patient is already suffering from chronic catarrh, excess of strong alcohol and an overdose of an irritating drug are common causes. In many cases the irritant is a toxin produced by the action of bacteria outside the body or in the stomach, the organisms being introduced in the food or water, several individuals being often simultaneously affected. The toxins of uræmia and those produced in influenza, scarlet fever, septicæmia and other acute infections may be excreted into the stomach and give rise to gastritis. The chlorine and other fumes introduced by the Germans in the war often resulted in the production of acute gastritis, the symptoms of which were overshadowed by the more serious pulmonary symptoms: in some cases hæmatemesis and in several others occult blood was present, showing the severity of the lesion.

Symptoms.—The symptoms start acutely soon after the entrance of the irritant into the stomach, but they may be postponed for several hours when the attack is due to a toxin produced by decomposition within the stomach. A sensation of fullness and discomfort is felt in the epigastrium; heartburn is common, and in severe cases there is acute pain; tenderness is diffuse and generally only moderate in degree. The abdomen may be distended. The appetite is completely lost, but thirst is excessive. The tongue is covered with a thick dirty fur, and there is an unpleasant bitter taste in the mouth. The patient constantly eructates, and the gas brought up is often foul-smelling. Vomiting, preceded by nausea, almost always occurs and gives more or less relief to the discomfort and pain. The food eaten at the previous meal is first rejected, mixed with mucus with but little or no

gastric juice; subsequently mucus with saliva, which is generally secreted in excess, bile, and occasionally small quantities of blood, are vomited. Severe constipation is present unless the irritant has also acted upon the bowels, in which case there is diarrhoea. The vomited matter contains no free hydrochloric acid, but is generally acid in reaction owing to the presence of lactic, butyric and other fatty acids; the saliva and mucus present may, however, give it an alkaline reaction. Microscopically leucocytes, epithelial cells, bacteria and sometimes blood are found.

The patient is pale, prostrated, and complains of headache and thirst. These symptoms are most marked in infective cases, when the patient may also be drowsy and even delirious. The temperature is generally slightly raised, but it may be high, especially in children, and the pulse is rapid. The urine is concentrated and may contain a trace of albumin. Herpes labialis is sometimes present.

Diagnosis.—In severe pyrexial cases the symptoms may simulate the onset of an acute infection, such as typhoid fever, but the rapid improvement soon makes the diagnosis clear. I have seen cases in which the pain, tenderness and rigidity were so severe that considerable doubt was felt at first whether a gastric ulcer might not have perforated.

Prognosis.—Recovery generally takes place within 24 or 48 hours, but in toxic and infective cases the acute symptoms may persist for several days, at the end of which they may suddenly disappear. Occasionally the condition passes into chronic gastritis, or the stomach may remain irritable for a considerable period. Acute gastritis often gives rise to complete achylia, even if no symptoms follow the acute attack.

Treatment.—The patient should be kept warm in bed with hot fomentations on the abdomen. If the stomach is not spontaneously emptied, vomiting should be induced by drinking half a pint of warm water, in which 1 drachm of sodium bicarbonate has been dissolved; when this fails the stomach should be washed out.

Chloroform water often relieves the nausea; castor oil, followed, if necessary, by a saline aperient should be administered if there is constipation. No other drugs need be given except in the rare cases in which very severe pain persists after the stomach is empty, when an injection of morphine may be required. Nothing but water, which may be flavoured with tea or lemon, should be taken until all the acute symptoms have disappeared; sweetened arrowroot made with water may then be given, and, as the appetite returns and the tongue cleans, dilute citrated milk, farinaceous food, eggs, and lastly fish, chicken and meat can be added to the diet. If the appetite does not return by the end of a week, an acid and bitter mixture should be given. A test meal should be given when the patient is convalescent, as if achylia has developed the continuous use of hydrochloric acid may prevent the development of various complications at a later date.

(b) ACUTE SUPPURATIVE GASTRITIS

Ætiology.—This very rare disease is due to the invasion by streptococci, or less frequently pneumococci, staphylococci or *B. coli*, of the submucous tissue through a carcinomatous ulcer, or still more rarely through a chronic ulcer or the wound left after an operation on the stomach. In exceptional

cases the point of invasion cannot be recognised. The condition may also occur in pyæmia, anthrax and small-pox.

Symptoms.—Epigastric pain and tenderness are severe. Vomiting is always present; the vomited matter may contain pus owing to the rupture of a localised abscess into the lumen of the stomach. Peritonitis generally supervenes in the course of 2 or 3 days. The general symptoms present are those common to severe infections.

Prognosis.—A local submucous abscess may burst inwards and spontaneous cure result, but more commonly it ruptures outwards, producing general peritonitis. Diffuse suppurative gastritis always ends in peritonitis.

Treatment.—In very rare cases a localised abscess has been treated successfully by operation.

(c) ACUTE PHLEGMONOUS (TOXIC) GASTRITIS

Ætiology.—Phlegmonous gastritis results from the ingestion of irritant poisons, such as concentrated acids and alkalis, arsenic, antimony and phosphorus.

Symptoms.—The local symptoms are similar to those of acute suppurative gastritis, except that the vomited matter frequently contains blood and sometimes sloughs. The patient is collapsed and may become comatose, the exact symptoms depending upon the nature of the poison.

Prognosis.—Death frequently occurs from shock, general peritonitis, or the effect of the poison on other parts of the body. If the patient recovers, the mucous membrane is always more or less atrophied, and pyloric obstruction frequently develops.

Treatment.—An attempt should be made to dilute and neutralise the poison. When this is impossible the stomach should be washed out. Morphine should be injected to relieve pain and to keep the patient quiet.

CHRONIC GASTRITIS

Ætiology.—Chronic gastritis is generally due to repeated or long-continued chemical or mechanical irritation of the gastric mucous membrane. The most common chemical irritant is alcohol, which is most harmful when taken in a concentrated form on an empty stomach. Less frequently excess of strong tea or coffee, curry and other spices, and drugs, such as purgatives, mercury, copaiba and creosote, cause gastritis. Prolonged contact of less irritating food may have the same effect; consequently very large meals, food taken late at night, and stasis due to pyloric obstruction lead to catarrh. The irritating and infective secretions swallowed in pyorrhea alveolaris, chronic pharyngitis, tonsillitis and sinusitis, and by children with adenoids, are common causes. Coarse food and food which is insufficiently masticated, owing to rapid eating or lack of teeth, lead by mechanical irritation to gastritis.

Chronic catarrh may also follow acute gastritis. It is very common in carcinoma of the stomach, and may also occur in very chronic cases of ulcer. Lastly, it is a common result of phthisis, especially in the later stages, and

of the congestion of the mucous membrane in diseases of the heart, lungs and liver.

Symptoms. The symptoms develop very gradually or begin after an acute attack. A sensation of pressure and fullness is felt in the epigastrium immediately after meals; it is often accompanied by pain between the shoulders. It is most severe and prolonged after large meals, and may be absent when only fluids are taken. It is relieved by eructation and vomiting, and the patient sometimes makes himself vomit by putting his fingers in his throat. Tenderness is slight and ill-defined. Heartburn and acid eructation are rare, except in the early stages. A test meal shows the presence of mucus in every fraction. In chronic cases achlorhydria is often present; this is partly a result of the thick layer of mucus which sticks to the surface of the gastric mucous membrane, blocking the mouths of the glands, and partly of the neutralisation by the alkaline mucus of any free acid which gains access to the lumen of the stomach. Consequently a second test meal given immediately after thorough lavage of the stomach often shows that the acid is secreted in normal or almost normal quantity. In rare cases true achylia results from atrophy of the mucous membrane caused by prolonged and severe chronic inflammation. The size of the stomach and its motor functions are generally normal. The appetite is generally poor, the tongue is furred, chronic pharyngitis is present, especially in alcoholic cases, the patient complaining of an unpleasant taste in the mouth, and the breath is foul. Nausea, often accompanied by salivation, is common; it may be followed by vomiting of small quantities of half-digested food and mucus. In alcoholic gastritis vomiting in the early morning is frequent, and the patient has no appetite for breakfast; the vomit consists of alkaline, mucous fluid, largely composed of saliva and swallowed secretion from the inflamed pharynx and oesophagus.

The general health may remain good for years, but in chronic cases the patient is thin and sallow and complains of a feeling of slackness, general malaise, headache and insomnia, the symptoms varying with the condition of the stomach, and he frequently becomes hypochondriacal.

Diagnosis. Chronic gastritis should only be diagnosed if a test-meal has shown that excess of mucus is secreted by the gastric mucous membrane. If there is wasting, cancer may be simulated; in such cases an X-ray examination often settles the diagnosis. The presence of occult blood in the stools is uncommon in chronic gastritis but constant in cancer, and the good effect of dieting is lasting instead of temporary. The definite relationship between the amount of discomfort and the quantity and quality of the food distinguishes catarrh from nervous dyspepsia, in which the symptoms are also more irregular. The presence of excess of mucus in the vomit or after a test-meal is conclusive evidence against uncomplicated nervous dyspepsia, but only if it is certainly of gastric origin and not swallowed.

Prognosis.—A patient with chronic gastritis is always liable to attacks of acute and subacute gastritis, and the excessive vulnerability of the mucous membrane may persist to a less extent after the chronic condition has disappeared.

Treatment.—Everything concerned in the production of the condition must be removed as far as possible. The teeth should be put into perfect order and artificial ones supplied when necessary. When the tongue is

furred, it should be frequently cleaned in order to remove the unpleasant taste from the mouth and improve the appetite. The food should be thoroughly masticated and eaten at regular hours; the last meal should be taken three hours before going to bed. The patient should rest for at least half an hour after meals, and whenever he is at all tired for half an hour before meals. Alcohol should be entirely prohibited. Tea must be weak and freshly brewed, and coffee only drunk if mixed with an equal quantity of milk. All condiments must be avoided, as well as tough meat, skins and pips of fruit, salads, pickles and green vegetables, except in the form of purées. In severe cases it may be necessary to start with a stricter diet, which is gradually increased in the manner described in the treatment of gastric ulcer.

The diet and regular life at an inland health resort are often useful, drinking of the saline and alkaline waters probably contributing to the good results.

A bitter and alkaline mixture before meals increases the appetite and stimulates the secretion of gastric juice. If true achylia is present, as distinct from achlorhydria caused by neutralisation with excess of mucus, hydrochloric acid should be given (see p. 528). Achlorhydria secondary to the excess of mucus should be treated by washing out the stomach every morning before breakfast. The best solution for the purpose is hydrogen peroxide; the oxygen given off dislodges the mucus from the surface of the mucous membrane and perhaps stimulates the secretion of gastric juice. As improvement takes place the strength of the hydrogen peroxide can be gradually increased from 1 to 4 drachms to the pint, as less froth is produced. The treatment should be continued until no more mucus is washed away and a test meal shows that none is present in any fraction and free acid is again present. The bowels should be kept regular by taking honey, fruit jelly, stewed fruit, from which pips and skins must be carefully separated, and purées of green vegetables, but aperients should be avoided if possible. The constipation present is often due to dyschezia, which should be treated by re-education. If these means are insufficient, liquid paraffin should be given, and, if necessary, an infusion of senna pods.

GASTRIC AND DUODENAL ULCER

Pathology.—An ulcer of the peculiar type found in the stomach occurs nowhere else in the body except in the duodenal bulb and the part of the jejunum immediately adjoining the stoma of a gastro-jejunostomy. The one common feature of these three situations is the presence of gastric juice. But gastric juice will not digest the normal mucous membrane. Only if a small area of mucous membrane has had its vitality so lowered that it can no longer resist digestion does a superficial erosion form, which may develop into an acute ulcer, and ultimately into a typical chronic gastric or duodenal ulcer. The impaired vitality is probably always the result of the action of toxins, which are generally of bacterial origin. The most important sources are the teeth, tonsils, nasal sinuses and the appendix. Bacterial toxins produced by *pyorrhœa alveolaris* and by root infection may be excreted by the gastric or duodenal mucous membrane after absorption into the blood stream and may lead to local necrosis, just as the toxins produced by burns may in rare instances damage the duodenal mucous membrane. In 24 hours very large quantities of pus are produced by the

ulcerated areas in pyorrhœa alveolaris, and as all of this is swallowed, it can hardly be doubted that it leads to secondary infection of gastric and duodenal ulcers, especially in the night, when it is no longer diluted by the food, and when the bacteria are less likely to be destroyed by acid gastric juice. Septic foci in the tonsils, pharynx and nasal sinuses probably act in the same two ways. The association of chronic appendicitis with both acute and chronic gastric and duodenal ulcer is too common to be a coincidence, and the greatly diminished tendency to relapse, especially of acute ulcers, following removal of the appendix without interfering with the ulcer, shows that the appendicitis is the primary condition. Chronic infection of the gall-bladder is probably another cause of gastric and duodenal ulceration. When streptococci isolated from the deeper layers of chronic ulcers are inoculated into animals they produce ulcers in a large proportion of cases—much more frequently than streptococci obtained from other sources. Moreover, the streptococci obtained from infected teeth or tonsils of patients suffering from chronic gastric or duodenal ulcer have the same effect. This indicates that although these streptococci cannot be recognised by their cultural properties they have acquired a special destructive action on the gastric and duodenal mucous membrane.

The occurrence of ulceration is rare in comparison with the frequency of the various exciting causes just described, because it is unlikely for an acute ulcer to become chronic unless the stomach has the physiological characteristics which predispose to the production of gastric or duodenal ulcer. There appears to be something in the nature of an "ulcer diathesis," which makes certain individuals and sometimes two or more members of the same family liable to develop a chronic gastric or a duodenal ulcer throughout their lives. It may depend upon a peculiar anatomical configuration of the smallest arterioles, or less probably upon deficient alkalinity of the tissues, either of which would interfere with the healing of an acute ulcer. In addition to this general ulcer diathesis, there appears to be a special gastric ulcer diathesis associated with a long stomach, and a duodenal ulcer diathesis associated with hyperchlorhydria and a short and rapidly emptying stomach, a condition I have called the "hypersthenic gastric diathesis." As a consequence of the latter the duodenal bulb is kept constantly filled with exceptionally acid chyme, and neutralisation with the alkaline duodenal juice is impossible; even when the stomach is empty, gastric juice continues to be secreted, and passes rapidly into the duodenum without being diluted and partially neutralised by admixture with food.

The tendency to develop a duodenal ulcer is increased by excessive smoking; the nicotine apparently acts through the autonomic nervous system and increases the hypermotility and hyperchlorhydria.

Chemical irritants, such as alcohol, especially when taken on an empty stomach, vinegar, the acids of unripe fruits, and mustard, pepper and curry, taken in excess, interfere with the healing of an acute or chronic ulcer. Insufficiently masticated food, and hard indigestible particles, such as rips and skins of fruit, fibres of raw vegetables, such as celery, and nuts have a similar effect.

One of the oldest theories of the origin of gastric ulcer was that the occlusion of small blood vessels led to local anæmia of the mucous membrane, which allowed digestion by the gastric juice to occur. It seems not unlikely

that vasomotor spasm may be one factor, as something of this kind could alone explain the undoubted influence of sudden change of temperature in the production of relapses of gastric and especially of duodenal ulcer.

ACUTE ULCER

Ætiology.—Acute ulcer, especially of the stomach, occurs most frequently under the conditions already described. It was formerly most common among anæmic young women, but owing to the much smaller incidence of chlorosis in recent years it is now almost as common in young men, and it may also occur in later life.

Symptoms.—Acute ulcer gives rise to no symptoms unless it causes hæmorrhage, which is often profuse but very rarely fatal, or, in exceptional cases, perforation. Hæmorrhage or perforation occurring without any previous indigestion is thus usually due to an acute ulcer. In some cases it may be associated with the dyspepsia caused by chronic appendicitis, or gastritis secondary to oral or pharyngeal infection, but the gastric symptoms are not caused by the ulcer.

Prognosis.—Acute ulcers can develop into chronic ulcers, but the majority heal rapidly, leaving so small a scar that neither pyloric obstruction nor any deformity in the shape of the stomach results. There is a great tendency to relapse, but the patient is able to take a full diet without discomfort between the attacks.

Treatment.—For the treatment of the hæmorrhage, see Hæmatemesis. The diet should be rapidly increased until everything but obviously indigestible food is taken. The patient should be kept in bed until 3 weeks after the cessation of hæmorrhage and pain. The teeth should be put in good order, and the patient should be taught to eat slowly and chew thoroughly. If the tonsils are infected they should be enucleated, and any other source of infection in the nose or pharynx should receive treatment. If the appendix or gall-bladder is diseased, it should be removed, but a gastro-jejunostomy should on no account be performed for an acute ulcer. Iron and arsenic should be given if anemia is present.

CHRONIC GASTRIC ULCER

Ætiology.—Men are rather more often affected than women, but when on the lesser curvature giving rise to hour-glass stomach they are rare in men; no age is exempt, but most cases occur between 30 and 50.

Symptoms.—The onset is generally insidious, the symptoms first appearing after big or indigestible meals, and gradually becoming more easily produced. The pain, which is often burning in character, and may be very severe, is situated in the middle of the epigastrium and may radiate upwards and to the back; it is much more marked after indigestible food, and generally disappears with a milk diet. In ulcers situated near the cardia it begins almost immediately after meals, and in pre-pyloric ulcers 2 or 3 hours after, intermediate intervals indicating an ulcer on the lesser curvature of the stomach. The pain generally disappears spontaneously after about an hour. It is completely relieved by emptying the stomach by vomiting or by a tube, and by alkalis; food generally produces less complete relief than

with duodenal ulcer. Partial relief is generally also obtained on lying down and by warm applications to the epigastrium. A small area of tenderness, the position of which is constant for each case, is present in the epigastrium, and occasionally to the left of the spine, especially when the ulcer has eroded the pancreas. The tenderness is greater than in any other gastric disease, and is most marked or only present when there is spontaneous pain. It is associated with rigidity of the left rectus. A definite area of cutaneous hyperæsthesia is rarely present, except in young women, in whom the possibility that it has been produced by unconscious suggestion on the part of the observer in the course of his examination should always be remembered.

With increasing pain vomiting appears; it occurs at the height of the pain, a small quantity of acid fluid with a little well-digested food being brought up. As a result of dieting the vomiting generally becomes less frequent, but if the pain is severe it is often self-induced by the patient.

Occult blood is frequently found in the stools and vomited material, but disappears rapidly when the patient is dieted. In a much smaller proportion of cases obvious hæmatemesis occurs; when the blood is abundant it is bright in colour and the stools are tarry; when less abundant it is coffee-coloured and mixed with food and is only recognisable in the stools by chemical examination. Mæna may also occur without hæmatemesis. The appetite is good at first, but fear of pain may lead to diminished intake of food, with consequent loss of weight and weakness; in some cases, however, the relief given by food encourages the patient to eat heartily. The tongue is clean, but constipation is commonly present.

In uncomplicated cases there may be some delay in evacuation owing to reflex achalasia of the pyloric sphincter. A spasmodic stricture is often observed with the X-rays in the centre of the stomach, when the ulcer is situated on the lesser curvature. Conclusive evidence as to its position is always obtainable by the discovery of a "niche" or diverticulum filled with opaque salt, which has found its way into the crater of a chronic ulcer; this is always the site of the maximum degree of deep tenderness.

A test meal gives no constant result, but hyperchlorhydria is much more common than in normal individuals. In very chronic cases hypochlorhydria and even achlorhydria may be present, but these are due to associated chronic gastritis, and a second test meal given after the ulcer has healed shows a considerable increase in acidity and often hyperchlorhydria, as the treatment also leads to the disappearance of the gastritis.

Diagnosis.—Hæmatemesis or the presence of occult blood in the stools excludes all other gastric disorders except cancer. The possibility of cirrhosis of the liver, in which the gastric symptoms are those of chronic gastritis and have none of the regularity of those caused by ulcer, and splenic anemia, in which no other gastric symptoms occur, should always be considered in a case of hæmatemesis. In cancer occult blood is constantly present in the stools in spite of diet, free hydrochloric acid is absent in 60 per cent. of cases; a chronic ulcer may give rise to a palpable tender tumour, but less frequently than cancer, in which anorexia and wasting out of proportion to the diminished intake of food are also likely to be present. In nervous dyspepsia the pain and tenderness are irregular in position, time of onset, and relation to the quantity and quality of food, and are

less constantly relieved by alkalis. In chronic gastritis discomfort rather than pain is present; it generally begins directly after meals, and there is no localised tenderness. For the diagnosis of duodenal from gastric ulcer, see Duodenal Ulcer. The gastric symptoms associated with cholecystitis and chronic appendicitis may simulate ulcer, but the relation of the pain to the nature and time of meals is less regular, and less relief is given by alkalis; tenderness is present over the gall-bladder or in the right iliac fossa respectively in addition to the epigastrium. It should be remembered that cholecystitis and still more frequently chronic appendicitis may be associated with gastric ulcer. With good technique it ought always to be possible to settle the diagnosis of a chronic ulcer by means of the X-rays.

COMPLICATIONS.—Perforation may lead to general peritonitis or a localised abscess; if the perforation occurs slowly, especially if it is posterior, adhesions develop, which occasionally give rise to pain. It is rare for a gastric ulcer to be situated sufficiently near the pylorus to cause obstruction on healing. The cicatrization of a large ulcer in the body of the stomach may cause hour-glass constriction. Very chronic ulcers may in rare instances become carcinomatous, but such ulcers may form definite tumours without being malignant. Earlier onset of pain, which is less liable to temporary improvement, increased severity of pain and disappearance of heartburn in the case of cancer, and increased frequency of vomiting point to the probable onset of one of these complications.

CHRONIC DUODENAL ULCER

Ætiology.—The ætiology of chronic duodenal ulcers is much the same as that of chronic gastric ulcers, but the greater frequency in men than in women is much more marked. Although acute ulcers appear to be less common in the duodenum than the stomach, chronic ulcers occur three or four times more frequently in the duodenum.

Symptoms.—The earliest symptom is generally a sense of discomfort or fullness 3 hours after the largest meals. This is gradually replaced by pain, which occurs between 2 and 4 hours after every meal, the interval being longer the larger the meal. It frequently wakes the patient in the early part of the night, particularly if the last meal was finished less than 3 hours before going to sleep. It is generally situated in the middle line, rather nearer the umbilicus than the ensiform cartilage; it may radiate to the right or be situated on the right side only; in rare cases it is on the left. The pain is often associated with a feeling of hunger and is relieved by taking food; it is therefore commonly known as "hunger-pain." It is also relieved by alkalis and when the stomach is emptied by means of a tube or by vomiting; vomiting is, however, rare in uncomplicated cases, though regurgitation of mouthfuls of scalding, very acid, fluid may occur when the pain is at its height. Periods of hunger-pain lasting some weeks or months alternate with periods of more or less complete freedom from symptoms. The attacks are much more common in cold weather than in hot, but the autumn and early spring are generally more trying months than winter. Attacks are liable to be brought on suddenly by exposure to cold, by worry, an indigestible meal, or excessive smoking or drinking.

Hæmorrhage may never occur, but in the majority of cases occult blood is found from time to time in the stools. Severe hæmorrhage is less frequent; it always results in melæna, and may also give rise to hæmatemesis. The appetite remains good and the patient does not lose weight or strength.

The stomach is found by the X-rays to be short, the greater curvature rarely reaching the level of the umbilicus, and the stomach empties itself with unusual rapidity. In chronic cases reflex achalasia of the pyloric sphincters may lead to delayed evacuation and consequent increase in size of the stomach, the

greater curvature of which then reaches below the umbilicus, but after successful medical treatment the high position and rapid evacuation return unless some organic narrowing follows the healing of the ulcer. Irregularity in the outline of the duodenal bulb, due partly to the deformity caused by the ulcer itself and partly to secondary spasm, is always found, and affords conclusive evidence that an ulcer has been present, but unless it is tender or a definite mark is seen the deformity may be due simply to the scar of a healed ulcer. Constipation is almost invariably present. A test-meal generally shows the presence

of hyperchlorhydria (Fig. 18); if a low curve is obtained with a fractional test-meal this is generally due to associated gastritis and is replaced by a high curve if the meal is repeated when treatment has resulted in healing of the ulcer and disappearance of the gastritis.

Diagnosis.—When the symptoms have only been present for a short time an actual ulcer is not as a rule present, but a pre-ulcerative duodenitis, which is likely to result in ulcer if not adequately treated. Excessive smoking and over-fatigue may give rise to almost identical symptoms in individuals with the hypersthenic gastric diathesis, but the X-rays show no deformity of the duodenal bulb and occult blood is absent from the stools.

The diagnosis from gastro-ulcer depends upon the later onset of pain, the greater relief on taking food, the rarity of vomiting, the characteristic hyperchlorhydria curve obtained with a fractional test-meal, the frequent situation of pain and tenderness to the right of the middle line, the more

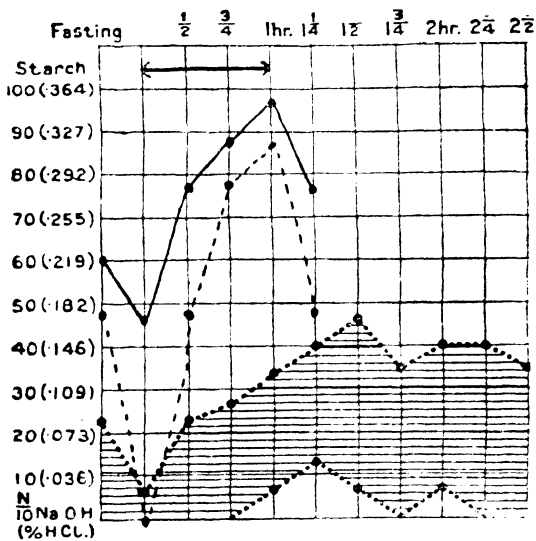

FIG. 18.—Fractional test-meal in case of duodenal ulcer, showing hyperchlorhydria and rapid evacuation. Continuous line, total acidity; dotted line, free HCl; shaded area, limits of free HCl in 80 per cent. of 100 healthy students.

frequent periods of complete freedom from symptoms, and the results of X-ray examination. The symptoms may closely resemble those of cholecystitis, but in the latter condition the pain is much less regular in its time relations, and tenderness over the gall-bladder and pain referred to the right shoulder are frequently present. In rare cases cancer and syphilis of the stomach may produce similar symptoms, but the X-ray examination and test-meal prevent a mistake in diagnosis.

COMPLICATIONS.—The inflammatory swelling round a large ulcer may lead to obstruction, the first symptom of which is generally vomiting. When vomiting is present and the stomach is found by the X-rays to be enlarged instead of small and to empty itself slowly, medical treatment must be prolonged, and even then may fail to give complete relief, as organic pyloric obstruction may follow the healing of the ulcer.

Perforation may occur and lead to general peritonitis, or, much less commonly, to a localised abscess. Sub-diaphragmatic abscesses due to duodenal ulcer are always to the right of the suspensory ligament; they may contain gas in distinction to those due to appendicitis, which are always free from it. Duodenal ulcers differ from gastric ulcers in showing no tendency to become malignant. This is probably due to the absence of the powerful peristaltic waves which rub hard particles of food against an ulcer in the stomach.

TREATMENT OF CHRONIC GASTRIC AND DUODENAL ULCER

As soon as a definite diagnosis of a chronic ulcer has been made, the patient should be kept in bed until there is strong evidence that the ulcer has healed. It is rare for this to occur in less than 4 weeks, and in very large and chronic ulcers 8 or 12 weeks may be required. For the treatment of hæmatemesis and the rules for commencing feeding after it, see Hæmatemesis (p. 537).

As a preliminary to the treatment of the actual gastric or duodenal ulcer the teeth should be put into perfect condition, and any infected focus in the nose or throat should be treated; throughout the treatment the mouth should be kept absolutely clean. If definite chronic appendicitis is present the appendix should be removed, but no operation should be performed on the stomach itself unless the ulcer is very large or is giving rise to mechanical difficulties owing to hour-glass contraction or pyloric obstruction.

The patient should be kept warm in bed throughout the treatment, but he should get up every day to have a bath and to open his bowels, the difficulties with which are greatly reduced if a bed-pan can be avoided. No smoking should be permitted during the period of strict treatment.

The object of treatment is to reduce the secretion of gastric juice as much as possible, and to keep the hydrochloric acid in the stomach completely neutralised throughout the day, and, what is almost invariably neglected, throughout the night. The evidence is conclusive that free hydrochloric acid prevents an ulcer healing, whatever additional factors may have contributed towards its production in the first instance. At the same time as much food as possible is required to maintain the patient's nutrition.

especially when he has lost much weight, as is often the case with gastric, though rarely with duodenal, ulcer. Finally, the food should be as unirritating in its mechanical and chemical characteristics as possible.

Between 5 and 7 ounces of milk are given every other hour from 8 a.m. to 10 p.m. inclusive. To each feed 10 grains of sodium citrate, which combines with the lime in the milk and consequently prevents the formation of irritating clots by the rennin of the gastric juice and is also a valuable alkali, dissolved in 1 or 2 drachms of emulsion of magnesia, are added; the latter contains 5 grains of oxide of magnesia to the drachm. This has the advantage over sodium bicarbonate in having four times its neutralising power, in giving off no carbon dioxide, which is liable to distend the stomach on reacting with the hydrochloric acid, in having a mild aperient action, and in producing a very much smaller secondary increase in secretion after the initial neutralisation than sodium bicarbonate, which is the most powerful stimulant of gastric juice in existence. The milk can be flavoured with tea, coffee or cocoa, and in cases requiring prolonged treatment the monotony of the diet can be relieved by the substitution of an equal quantity of custard, junket or arrowroot, to which apple or other fruit jelly may be added, for some of the feeds, and potato, artichoke or other vegetable purée for others, the latter having the advantage of containing vitamins, which help to prevent the patient's general health from deteriorating. Immediately before four of the feeds half an ounce of olive oil is taken. This inhibits the secretion of gastric juice; at the same time it supplies a digestible and absolutely unirritating food of very high nutritive value in a concentrated form. Immediately before three other feeds and last thing at night $\frac{1}{60}$ grain of atropine sulphate, or more if the patient can take it without unpleasant symptoms developing, which has a similar inhibiting effect, is given, and 2 or 3 ounces of cream are added to the morning feed.

With this treatment free acid is generally absent from the stomach throughout the day, except before breakfast and after 3 p.m. One drachm of tribasic magnesium phosphate should be given on waking, half an hour after the 3, 4 and 5 p.m. feeds and last thing at night, and at any other time the patient feels any "acidity." If the bowels act too much, some of this can be replaced by the corresponding calcium salt. They both have the advantage of not giving rise to alkalosis in spite of acting as efficient alkalis in the stomach. They can therefore be used in cases of renal insufficiency, though no sodium citrate nor magnesia is permissible.

If the ulcer is in the neighbourhood of the pylorus and is giving rise to any obstruction, continuous hypersecretion of gastric juice will occur throughout the night. It is then impossible for the ulcer to heal, and in the past it has been supposed that such cases required operation. But the obstruction is generally due entirely or in great part to surrounding œdema and inflammatory swelling and pyloric achalasia, and in such cases, if the ulcer can be caused to heal, any scarring produced is insufficient to give rise to obstruction. At 11 p.m., immediately before the last alkaline powder is given, the stomach is completely emptied by Senoran's evacuator; if not more than 2 ounces of fluid are present on two consecutive nights this can be discontinued. A double dose of atropine sulphate is then given in order to inhibit the further secretion of gastric juice. In most cases the continued nocturnal secretion is rapidly controlled by this treatment. Before

commencing treatment in any cases of partial pyloric obstruction the blood uræa should be estimated.

If the patient is constipated, the dose of magnesia should be increased, and if the bowels are not opened on 2 consecutive days, an enema should be given. If diarrhœa occurs, the dose of magnesia should be reduced and that of tribasic calcium phosphate reduced.

The strict treatment just described should be continued until for 3 weeks the patient has had no spontaneous pain, no trace of tenderness has been present, no occult blood has been found in the stools, and the X-rays no longer show the presence of an ulcer crater. The pain and tenderness generally disappear within 48 hours; the other signs of healing appear considerably later, the exact time depending upon the size and age of the ulcer and its proximity to the pylorus.

The diet can now be rapidly increased until at the end of a week everything is taken with the exceptions I shall presently enumerate. Minced meat should be avoided, as the patient should be taught the importance of chewing his food so thoroughly that it is fluid in consistence by the time he swallows it; this has the further advantage that the food is mixed with a sufficient quantity of alkaline saliva.

It is not difficult to cause an ulcer to heal by suitable treatment in bed, but the predisposing exciting cause, which led to the ulceration, may still be present and persist for many years. Special precautions are therefore required to prevent a recurrence, and it is advisable to give written instructions for the patient to follow.

The teeth, which should have been put into thoroughly good condition at the commencement of treatment, should in addition be overhauled twice a year so that the slightest tendency to pyorrhœa alveolaris or apical infection can be kept in check. The patient should eat slowly and masticate thoroughly; it is a good plan to give him solid food during the last days he remains under strict observation, so that he may get into the habit of eating slowly, for when the habit is once acquired, it is easy to continue in the same way. It should be impressed upon busy men that when they have no time to sit down to a proper meal it is better to drink some milk or eat some chocolate than to bolt some less digestible solid food. Tough meat, new bread and other articles of diet which cannot easily be chewed to a fluid consistence should be prohibited. Thus the patient should avoid the pips and skins of fruit, whether raw, cooked, or in jam, cake or puddings, and pickles, salads and all uncooked vegetables, such as celery; green vegetables are best given as purées with butter. No strong tea or coffee, no aerated drinks and no alcohol should be allowed, except a very little diluted whisky with meals for those who feel the need of it. Condiments, vinegar and unripe and acid fruit, high game, sausages, curry and made-up dishes should be prohibited. Ices and very cold and very hot drinks should be sipped and kept sufficiently long in the mouth for them to approximate to the body temperature when they reach the stomach. The patient should only be allowed to smoke in moderation. He should remain strictly on this régime until he has been free from symptoms for 2 years, and should follow it in a modified form for the rest of his life.

The bowels should be kept regular; this can be done most conveniently by means of light oxide of magnesia, which should be given after each meal.

as it helps to neutralise the free acid in the gastric contents. The most convenient way to take it is in a fluid preparation, containing 5 grains of magnesia to the drachm, from half a drachm to half an ounce being required as a dose. If the magnesia is insufficient to control the constipation, a tablespoonful of liquid paraffin may be given after one or more meals.

If hyperchlorhydria is present, it is advisable for a time to continue to give a tablespoonful of olive oil half an hour before meals to reduce the acidity. Patients should always have an alkaline powder by them, so as to be able to take just enough to keep themselves perfectly comfortable at the slightest suspicion of gastric discomfort. They should be warned of the danger of recurrence, and should be told to go to bed on a milk diet at the first indication of a return of symptoms. If they do this, treatment for 24 hours is often sufficient to ward off an attack. If, on the other hand, they wait until the symptoms become fully developed, a prolonged stay in bed will be required.

An operation should be advised under the following circumstances :

1. At the earliest moment after a perforation.
2. For pyloric obstruction without symptoms of active ulceration.
3. For pyloric obstruction with symptoms of active ulceration, which is still found to be present after 3 weeks of medical treatment.
4. For a gastric ulcer causing organic hour-glass contraction sufficiently severe to produce 6-hour stasis in the proximal segment.

5. When the symptoms recur after one or more courses of thorough medical treatment followed by adequate after-treatment ; the number of such courses which may be tried depends upon such circumstances as the age, social position, occupation and place of residence of the patient ; thus the older a patient, the better his social position, the less strenuous his occupation and the less important occasional absences from business, and the warmer and more equable the climate, the less urgent is the necessity for operation. In my experience recurrence is very unusual in the absence of pyloric obstruction, if the ulcer has once completely healed, all septic foci have been removed, and the after-treatment is conscientiously carried out.

6. As it is very rare for death to occur from a single gastric hæmorrhage, no operation should be performed, except when severe hæmorrhage recurs more than once, especially in patients past middle age and it appears probable that the blood comes from a sclerotic vessel which cannot contract. An attempt should then be made to excise the ulcer or, if this is impossible, to ligature the bleeding point ; failing this also, a series of sutures should be tied round the ulcer so as to cut off as much as possible of its blood supply. Whenever possible, it is best to wait until the patient has got over the initial collapse following a severe hæmorrhage ; the patient should be transfused before, and if necessary, a day after the operation.

7. When for any reason, such as the persistence of pain or of occult blood in the stools, it appears possible that a growth is present, the abdomen should be explored, and unless a growth can be excluded with certainty, partial gastrectomy should be performed.

If the ulcer is in the pyloric region, but not otherwise, gastro-enterostomy is sufficient. For ulcers situated in other parts of the stomach, partial gastrectomy appears to be the most satisfactory operation. A gastro-gastrostomy is the ideal operation for organic hour-glass contraction.

After any operation for gastric or duodenal ulcer, the patient should follow out exactly the same after-treatment as after medical treatment, or various ill results, the most serious of which is the production of a gastro-jejunal or a jejunal ulcer, may ensue.

TUBERCULOSIS OF THE STOMACH

Tubercle of the stomach is very rare. In miliary tuberculosis the mucous membrane may be involved, but no symptoms are produced. In advanced pulmonary tuberculosis a tuberculous ulcer may form, generally near the pylorus. The symptoms are indistinguishable from the dyspepsia common in such cases, unless hæmatemesis occurs; this may, however, be due to the presence of a simple ulcer. I have seen one case in which the symptoms and radiological signs suggested the presence of a simple ulcer on the lesser curvature which was becoming malignant; achlorhydria was present and occult blood was found in the stools. Partial gastrectomy was performed; an ulcer was found and the surrounding mucous membrane was thickened as a result of a definitely tuberculous infection, which appeared, however, to be secondary to a simple chronic ulcer.

SYPHILIS OF THE STOMACH

Syphilis of the stomach is probably less rare than is generally supposed. In one specimen spirochaetes were actually discovered (McNee). It has been recorded as developing at any time between 4 and 40 years after infection. A gummatous infiltration of the submucous tissue occurring on the lesser curvature near the pylorus may form a tumour suggestive of a chronic ulcer or cancer; in either case it may produce pyloric obstruction or an hour-glass stomach. Free hydrochloric acid may be absent, and occult blood is occasionally found in the stools, but obvious hæmorrhage is rare. The possibility of syphilis should always be considered when symptoms suggestive of cancer are present; even if there is no history or other evidence of syphilis the Wassermann reaction should be tested. The diagnosis would be confirmed by the rapid improvement with anti-syphilitic treatment in spite of the failure of other measures. In one case typical symptoms of duodenal ulcer were present, but no improvement had followed prolonged treatment of the usual kind. Achlorhydria was then discovered to be present instead of the hyperchlorhydria of duodenal ulcer, and there was no duodenal deformity; the Wassermann reaction was positive, and rapid recovery followed anti-syphilitic treatment.

CARCINOMA OF THE STOMACH

Ætiology.—Carcinoma of the stomach occurs most frequently between the ages of 40 and 60, and is rare before 30 and after 70. It is twice as common in men as in women. Sarcoma occurs with one-fortieth the fre-

quency of carcinoma; males and females are equally affected, and the disease is relatively more frequent under the age of 30 than carcinoma.

Clinical and pathological evidence shows that carcinoma may occasionally develop from chronic gastric ulcer; thus in about 6 per cent. of chronic ulcers excised by operation, which appear innocent to the naked eye, small areas are found in the margin which show microscopical evidence of malignant degeneration, and in about 16 per cent. of cases of obvious carcinoma there is pathological or clinical evidence that the disease followed a simple chronic ulcer (Stewart). I believe that a considerable proportion of the remaining cases are a sequel of chronic gastritis, which was either latent or caused comparatively trivial symptoms. The achlorhydria is not a result of the carcinoma, but of the gastritis which is always found involving the part of the mucous membrane not attacked by the growth. Carcinoma generally involves the lesser curvative or pre-pyloric area, less commonly the fundus in the neighbourhood of the cardia and the pyloric canal, and rarely other parts of the stomach.

Symptoms.—When an individual above the age of 40, who has hitherto had a good digestion, suddenly begins to suffer from gastric symptoms, the possibility of cancer should always be considered. In about one-fifth of the cases a long history of dyspepsia, suggesting gastric ulcer, is present, the local symptoms having recently altered in character and become continuous instead of more or less intermittent; at the same time the general symptoms become more marked. The patient suffers from epigastric discomfort or pain immediately or soon after meals. After a time the pain, which is generally dull and distressing, but not very acute, becomes continuous, but it is still aggravated by meals. In a small proportion of cases the pain comes on two or three hours after meals and is relieved by food, thus simulating duodenal ulcers, but there are never spontaneous remissions of symptoms and achlorhydria is generally present. At an early stage the appetite diminishes, the patient having a special repugnance for meat. This may be the first symptom, but in exceptional cases the appetite is maintained for a time. Anæmia and nausea occasionally precede all other symptoms by some months. Flatulence is commonly present, the gas brought up being at first odourless, but subsequently foul. Vomiting is generally present sooner or later; it is very abundant, and occurs at long intervals when the pylorus is involved; in cancer of the cardiac end of the stomach it immediately follows swallowing. Vomiting is commonly preceded by pain and nausea, both of which it temporarily relieves, but less completely than in gastric ulcer. The vomited matter contains blood more often than in gastric ulcer; it may have the appearance of "coffee grounds." Vomiting of blood alone is rare; but in a very large proportion of cases blood constantly oozes from the surface of the growth, so that one or more of the specimens obtained with a fractional test-meal may be obviously blood-stained, and all are likely to contain occult blood. The oozing is unaffected by diet, so that occult blood is generally present in every stool examined, however carefully the patient is dieted. The growth sooner or later involves the pylorus in a considerable proportion of cases; the special symptoms then present are described in the article on pyloric obstruction.

The patient rapidly loses strength and weight, the emaciation being more than can be accounted for by the vomiting and diminished intake of food.

In the late stages the disappearance of subcutaneous fat, loss of elasticity of the skin, œdema of the abdominal wall, back and ankles, and anæmia give the patient a characteristic cachectic appearance.

In the earlier stages nothing abnormal is found on abdominal palpation; but sooner or later a hard, moderately tender tumour is generally felt. It is often most palpable when the stomach is empty; but may only become obvious after meals.

The X-rays often show an irregular filling defect in the outline of the stomach, which coincides with the tumour if one is palpable, and often involves the greater curvature; the normal progress of the peristaltic waves is interrupted, sometimes before any obvious deformity is present.

If there is the slightest reason to suspect cancer a fractional test-meal should be given. The resting-juice often contains pus cells in excess of the leucocytes present in a specimen of spittle obtained at the same time, and even if the specimen is not obviously blood-stained red corpuscles are generally found on microscopical examination. In 60 per cent. of cases complete achlorhydria is present, and in at least another 20 per cent. there is hypochlorhydria; in most cases secondary to ulcer free acid is present, sometimes actually in excess. If achlorhydria is present, but not otherwise, the resting-juice generally contains lactic acid.

Secondary deposits frequently occur in the liver, and the symptoms they give rise to may be the most prominent clinical manifestation. Direct spread to the peritoneum and omentum is frequent, and irregular abdominal masses due to this cause are often palpable; ascites may occur as a result of the malignant peritonitis. A small gland just beneath the insertion of the left sterno-mastoid muscle is occasionally involved, and less frequently deposits may occur in the inguinal glands. The growth may spread along the urachus to involve the umbilicus, where a hard nodular mass can be felt. A rectal examination should always be made, as a deposit is not infrequently present in the recto-vesical or recto-vaginal pouch at a comparatively early stage.

Perforation may occur, general peritonitis being usually prevented by the presence of old adhesions, so that a local abscess forms; less frequently the colon becomes involved and a gastro-colic fistula results, the patient then rapidly dying from emaciation due to constant fecal vomiting and severe diarrhœa.

Other terminal complications are suppurative gastritis, pylephlebitis, suppurative parotitis, thrombosis, septic pneumonia, empyema and infective endocarditis.

Diagnosis.—Apart from the history and the discovery of a tumour, the X-ray examination is the most important means of distinguishing a growth from other gastric disorders. Occult blood is present in the stools for prolonged periods in many cases of ulcer, but achlorhydria is rare, and in the few cases of very chronic lesser curvature ulcer in which there is no free acid, it generally appears if the meal is repeated after washing out the stomach. Moreover, the characteristic X-ray appearance of an ulcer crater is quite different from the appearance produced by a growth. In gastric ulcer, the pain only begins at an interval after meals, and if present when food is taken it is at any rate temporarily relieved, whereas in cancer the pain begins directly after meals and is never relieved by food. Addison's

(pernicious) *anæmia* may closely simulate a growth of the stomach; the presence of occult blood in the stools is distinctive of the latter and does not occur in the former; the megalocytosis, high colour index, and positive indirect but negative direct van den Bergh's test of Addison's *anæmia* are in striking contrast with the absence of megalocytes, normal or low colour index, and negative van den Bergh's test of cancer, however severe the *anæmia* is. It should be remembered that an extensive growth may be present even with a hæmoglobin percentage of 100, and on the other hand that in extremely rare cases true Addison's *anæmia* may develop as a result of the achlorhydria associated with cancer of the stomach.

Prognosis.—The average duration of life after the appearance of the first symptom is 9 months. Temporary improvement may occur as a result of rest and careful dieting. Death is most frequently due to exhaustion; in other cases it results from one of the complications already mentioned.

Treatment.—Medical treatment is only palliative. The patient should be allowed to eat what he likes, but small, frequent and nutritious meals are most suitable. The mouth and tongue should be kept as clean as possible. Drugs must be employed for the relief of pain, and in the later stages injections of morphine are generally essential, and there should be no hesitation in giving very large doses.

If pyloric obstruction is present, the abdomen should be explored without delay, as even if a radical operation is impossible, gastro-jejunostomy produces marked, though only temporary, improvement. Apart from this indication, laparotomy should never be performed unless there is a distinct chance of removing the whole tumour. The presence of secondary deposits anywhere in the body and any marked degree of cachexia render the attempt quite useless. The most favourable cases are those in which a probable diagnosis has been made in the absence of a tumour or in the presence of a comparatively small, localised and movable one. At the operation a considerable margin of normal stomach and the lymphatic glands in the neighbourhood should be simultaneously removed.

PYLORIC OBSTRUCTION

Ætiology.—Pyloric obstruction is due in the vast majority of cases to the results of duodenal ulceration or to cancer. A duodenal ulcer situated in close proximity to the pylorus may as a result of the œdema and vascular engorgement at its edges lead to obstruction, which disappears when the ulcer heals. Sometimes more or less permanent obstruction is produced by contraction of the fibrous tissue formed by the cicatrization of the ulcer. As gastric ulcers are much less common than duodenal ulcers and are generally situated on the lesser curvature some distance from the pyloric canal, they rarely cause pyloric obstruction.

Cancer of the stomach rarely if ever originates in the pyloric canal, but in the majority of cases a growth beginning in the lesser curvature spreads so as finally to involve the pylorus. Syphilis of the stomach is a rare cause of pyloric obstruction. In infants obstruction may result from hypertrophy of the pylorus.

Spasm is often stated to give rise to pyloric obstruction, but the evidence

that it can do so is inconclusive, except in the hypertrophic pyloric stenosis of infants. On the other hand, there is no doubt that achalasia of the pyloric sphincter is a common result of duodenal ulcer, and less frequently of a lesser curvature ulcer, chronic cholecystitis and chronic appendicitis; it gives rise to definite obstruction, which is, however, intermittent, and never causes prolonged stasis or great distension. External pressure very rarely gives rise to pyloric obstruction, and simple adhesions between the pylorus and the neighbouring viscera do not, as a rule, interfere with the passage of food into the duodenum. In exceptional cases, however, cholecystitis may lead to such strong and extensive adhesions with the pylorus that a certain amount of obstruction results. Gastropotosis never causes pyloric obstruction (*vide* Visceroptosis, p. 671).

Symptoms.—In the early stages attacks of severe pain may occur at varying intervals after meals owing to the violent peristalsis of the stomach in its attempt to overcome the obstruction. Later, nothing more than an unpleasant sense of fullness is experienced, especially after meals, but if frequent vomiting or treatment by lavage prevents the stomach from being much distended, attacks of pain are likely to persist. With an ordinary diet vomiting occurs regularly every day, but this characteristic symptom is less marked if the patient takes a bland diet which leaves little or no solid residue. The vomiting generally occurs first in the afternoon or evening; but in the later stages, when dilatation has supervened, large quantities are vomited several times a day and often during the night. Articles of food may be brought up which have been eaten many hours or even days before. The odour is yeasty in non-malignant, and rancid in malignant cases. In malignant obstruction, excessive fermentation and putrefaction may give rise to very offensive eructation, and in rare cases this is the first symptom noticed by the patient. Wasting is progressive, and the tissues become abnormally dry and inelastic; in malignant cases a cachectic appearance is added to the simple starved appearance of non-malignant obstruction. The patient has generally little appetite, but complains of great thirst. The urine is scanty, and obstinate constipation occurs.

Pyloric obstruction occasionally gives rise to tetany and to symptoms of uræmia, especially in individuals with inefficient kidneys, as shown by an increase in the blood-urea. The symptoms are apparently partly of a true uræmic character and partly a result of alkalæmia, which is only in part due to the loss of hydrochloric acid in vomiting.

In addition to the symptoms already enumerated, others depending upon the cause of the obstruction, such as gastric ulcer or carcinoma, are, of course, also present.

Pyloric obstruction leads to distension of the stomach. The signs of this, together with the methods of distinction between the malignant and non-malignant cases, are considered in the section on the investigation of the alimentary canal.

Treatment.—The treatment of pyloric obstruction is gastro-jejunostomy. It is useless to waste time in well-marked cases with lavage or other medical treatment, as the improvement which follows operation is immediate and progressive. The immediate mortality of the operation can, however, be greatly reduced by preliminary medical treatment for a few days. The stomach is completely emptied every night by Senoran's evacuator. Small

quantities of custard, junket, and similar soft easily digestible foods are given during the day, but nothing to drink, saline solution being given by rectum or, if necessary, subcutaneously. By this means the tone of the stomach rapidly improves and the danger of severe intoxication due to alkalosis or other causes is overcome.

When the obstruction is only partial, and an active ulcer is present, the effect of medical treatment of the ulcer should be tried, as the obstruction is largely due to the surrounding inflammation, which disappears when the ulcer heals, and if the ulcer is not very large the scar produced may give rise to no obstruction.

ARTHUR F. HURST.

CONGENITAL HYPERTROPHY OF THE PYLORUS

Synonym.—Hypertrophic Pyloric Stenosis.

Definition.—This is a disease of early life, formerly believed to be a rarity, but now recognised as of not uncommon occurrence. It consists essentially in a great thickening of the pylorus, leading to gastric stasis, with all the symptoms that result from such a condition.

Ætiology.—The pathogeny of the disease is still obscure. The theory that it is simply a congenital malformation is not in harmony with the clinical facts, and the most generally accepted view is that it results from an overaction of the pyloric sphincter, the consequence of a lack of co-ordination between the gastric and pyloric mechanisms. There is some reason to suppose that the Anglo-Saxon and Teutonic races are more affected by the disease than the Latin, but it is exceptional to get a history of other cases having occurred in the family. Boys are affected at least four times as often as girls, and in a remarkably high proportion the patient is the first child of the family.

Pathology.—The most striking change is an immense thickening of the pylorus, due to overgrowth of its circular muscle-fibres. The stomach is dilated, its muscular coat somewhat hypertrophied, and the mucous membrane in a state of catarrh. The other post-mortem appearances are those usually met with in inanition.

Symptoms.—The child has usually been born at full time, after a natural labour, and in the majority of cases has been breast fed. For a week or two or longer all goes well, and then vomiting sets in. The vomiting is "projectile" in character, the stomach contents being violently shot out. The vomit is usually larger in quantity than the last meal, and is often mixed with mucus; the presence of any blood in it is very rare. Meanwhile the child steadily loses weight, but does not look really ill, and maintains his strength and activity. The bowels are obstinately constipated, and the motions small and dark.

The most characteristic sign of the disease is the presence of *visible gastric peristalsis*. On inspection of the abdomen waves of contraction can be seen sweeping across its upper part from left to right. Sometimes three such waves can be seen at once, each being about the size of a golf ball. The waves may not be seen unless the child has recently been fed, and if they are sluggish in appearing a little gentle stimulation below the left costal margin will often succeed in eliciting them. In many cases the overgrown

pylorus can be felt as a tumour by pinching up the deep structures in the right hypochondrium. Sometimes, however, it is so tucked up under the liver that it cannot be felt.

Complications and Sequelæ.—The complication most to be dreaded is the supervention of an infective diarrhœa, which in these cases is very apt to prove fatal. Some degree of acidosis is also apt to develop in severe cases. There are no sequelæ of the disease; if recovery takes place, it is complete and permanent, and indeed, many of the patients ultimately attain a degree of health and development beyond the average. The hypertrophy of the pylorus disappears.

Course.—The course of the disease varies greatly in different cases, and depends also to a large extent upon the treatment adopted, but unless operation is resorted to, it is always prolonged and recovery gradual. Even when the vomiting ceases, the weight may for long fail to rise, and the child may remain in a state of inanition, during which intercurrent disease may easily supervene.

Diagnosis.—This should not be difficult, provided the existence of the disease is remembered. The vomiting is distinguished from that of indigestion by its projectile character, and the coexistence of constipation is characteristic. The great diagnostic, however, is the presence of the visible peristalsis, and in the absence of this it is unwise to conclude that the disease is present. Mild cases of pyloric spasm may simulate true stenosis, but in these the symptoms are less severe, and definite waves of peristalsis are absent. The patient is often a girl. Stenosis of the duodenum from congenital malformation may simulate pyloric stenosis, but the symptoms in the duodenal cases date from birth, and bile is present in the vomited matter.

Prognosis.—It is very difficult to estimate the chances of recovery or the relative merits of different forms of treatment statistically. Much depends upon the severity of the particular case, but in general it may be stated that no case is so severe that recovery is impossible. Cases treated in private do much better than those seen in hospital.

Treatment.—There are two methods of treatment—medical and surgical. Medical treatment consists in washing out the stomach once or twice daily with warm water, and carefully regulating the feeding. If breast milk is not available, dilute peptonised milk is the best substitute, and should be given in quantities of one or two ounces every 2 or 3 hours, depending upon the degree of vomiting. Drugs are of no help. If under this treatment the vomiting ceases, and the weight begins to rise, good and well. If not, or if the symptoms have set in early and with great severity, operation should be had recourse to, Rammstedt's plan of splitting the pylorus longitudinally being the procedure to be preferred.

ROBERT HUTCHISON.

HOURLY GLASS STOMACH

Ætiology.—*Functional hour-glass stomach* occurs when atony is associated with ptosis of the stomach (orthostatic form). The sagging of the dropped organ when food enters it is so great that the lumen of its body is obliterated; when more food is eaten it is held up in the proximal segment of the stomach. The obstruction disappears on lying down (Fig. 19). When a gastric ulcer

is situated in the body of the stomach a spasmodic stricture may occur, which varies in degree from time to time, and disappears when the abdominal muscles are vigorously contracted. A less persistent spasm may occur as a reflex result of duodenal ulcer, disease of the gall-bladder, and appendicitis. *Organic hour-glass stomach* results from cicatrisation of a gastric ulcer (Fig. 20),

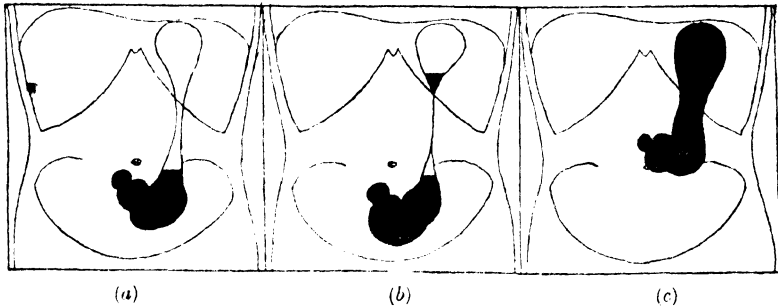

FIG. 19.—Orthostatic hour-glass constriction in dropped and hypotonic stomach. (a) Stomach partially filled; (b) hour-glass formed by weight of food in lower segment of stomach; (c) hour-glass constriction disappears with disappearance of ptosis on lying down.

and very rarely from syphilis or cancer. This condition is much more common in women than men.

Symptoms.—The symptoms of orthostatic and spasmodic hour-glass stomach are respectively those of atony and of the primary organic disease. In organic hour-glass stomach a history pointing to the existence of a chronic

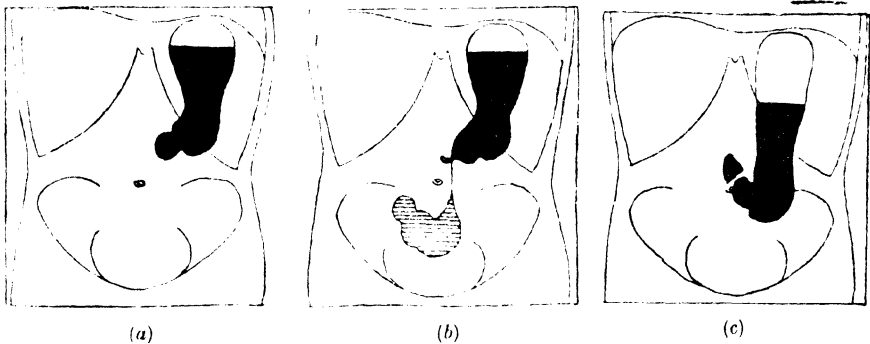

FIG. 20.—Organic hour-glass constriction of stomach. (a) Immediately after opaque meal, before anything has passed into lower segment; (b) Lower segment now filled; crater of chronic ulcer on lesser curvature filled with barium. (c) After gastro-gastrostomy.

gastric ulcer for many years can almost always be obtained. The symptoms are similar to those of pyloric obstruction due to ulcer, with the exception that the amount vomited is generally less, and greater relief is obtained on lying down. Visible peristalsis cannot be observed, unless the proximal segment is unusually large. The X-rays are the only reliable method of

diagnosis: the constriction can be seen whether the patient is standing or lying down, and in the former position the neck passes from a point somewhat above and to the right of the lowest part of the proximal segment. In most cases the crater formed by the ulcer on the lesser curvature can also be recognised.

Treatment.—In organic hour-glass stomach an anastomosis should be made between the upper and lower segments of the stomach (gastro-gastrostomy). Gastro-jejunostomy and partial gastrectomy should never be performed, unless pyloric obstruction is also present, in which case gastro-jejunostomy is required in addition to a gastro-gastrostomy.

ARTHUR F. HURST.

DISEASES OF THE INTESTINES

EXAMINATION OF THE INTESTINES

SIZE, SHAPE AND POSITION OF THE COLON

THE cæcum and iliac colon are the only parts of the bowel which are always palpable under normal conditions. In very thin individuals and in patients with very lax abdominal muscles the whole colon, except the splenic flexure and the pelvic colon, can often be felt. Apart from these conditions, the colon may become palpable when in a state of spasm or when filled with hard fæces, and tumours involving it can often be recognised by abdominal examination. In all intestinal cases a rectal examination must be made, as by this means not only the rectum but also part of the pelvic colon can be palpated. For a thorough investigation of the size, shape and position of the whole colon in the erect as well as the horizontal postures an X-ray examination after a barium meal is essential. The pelvic colon, and less frequently the descending and iliac colon, cannot always be seen satisfactorily, as they may only be full in the early morning, and defæcation empties them completely before it is convenient to make an examination. In such cases a barium enema renders all parts of the colon easily visible; the artificial distension produces a considerable amount of distortion, the error due to which can be overcome by making an additional examination after most of the fluid has been allowed to escape.

MOTOR FUNCTIONS

(a) *Palpation.*—In all cases of chronic constipation an abdominal and rectal examination should be made. It is important that no medicine or enemata should have been taken for 24 hours, but before this the colon should be emptied by whatever means are most effective. The abdomen and rectum can then be examined in order to ascertain whether there is an accumulation of fæces in any part of the large intestine after an attempt has been made to open the bowels without artificial assistance. An accumulation of fæces in the cæcum and ascending colon or in the transverse colon indicates stasis in these situations. If more than a very small quantity is found in the rectum and the patient has no desire to defæcate, dyschezia can

be diagnosed. On the other hand, if the rectum is almost or completely empty, the constipation must be due to delay in the passage through the intestines, except in the somewhat rare cases of dyschezia in which there is inability to pass fæces from the pelvic colon into the rectum: a mass of hard fæces can then generally be felt through the anterior wall of the rectum.

(b) *The charcoal method.*—By giving two or three charcoal lozenges with some food 8 hours after defæcation and observing after what interval black fæces are passed, the total time taken in their passage through the alimentary canal can be ascertained. If, for example, a patient's bowels have been opened at 8 a.m., charcoal should be given at 4 p.m. the same day. If some of the charcoal is not passed at the latest the second morning after it was taken, the patient must be regarded as constipated. The method has, however, the great disadvantage of giving no indication as to the part of the bowel in which stasis occurs.

(c) *X-ray examination.*—The only reliable means of determining whether a patient is suffering from chronic intestinal stasis, and of ascertaining exactly what parts of the alimentary canal are at fault, is a series of examinations with the X-rays.

Examination with the fluorescent screen gives much more information than is obtainable from radiograms. If the bowels are not spontaneously opened, an enema should be given on two consecutive mornings, on the second of which the opaque meal is taken. It is very important to discontinue the use of all aperients for at least 48 hours before the first examination, as the intestinal functions might otherwise be observed whilst still under their influence instead of under natural conditions. No more aperients and no enemata should be used till the examination is finished, but the patient should make an attempt each morning to open the bowels naturally. If the attempt is successful, the stools should be examined in order to ascertain whether any of the salt has been evacuated. During the whole period of the examination the patient should follow his usual occupations and take his ordinary diet, in order that the activity of the bowels may be investigated under natural conditions. An examination should be made in the morning and evening of each day until all or most of the barium sulphate has been passed in the fæces or has reached the rectum.

(d) *Barium enemata.*—Although an opaque meal is the best means of obtaining information of the motor functions of the colon, an opaque enema generally gives earlier and more exact information concerning the possible presence of a stricture, especially in the pelvic colon, which cannot often be satisfactorily examined by the former method. A suspension is made by adding barium sulphate to a mixture of a pint and a half of water with 1½ ounces of acacia mucilage. The patient lies on his back, and the fluid is run in from a funnel at a pressure of between 1 and 2 feet through a tube introduced just within the rectum. It often reaches the cæcum in a minute and almost invariably within 5 minutes. Patients rarely experience any difficulty in retaining the fluid until the examination is complete, when part can be run out through the tube by which it was introduced, the rest being evacuated in the ordinary manner.

An organic stricture of the colon generally obstructs the passage of the fluid, the shadow ending at the seat of the obstruction, which can be overcome only incompletely or not at all by waiting an additional 10 minutes, by increasing

the pressure of injection, by massage and by changes in posture. The flow of the enema is often prevented in cases of growth, long before there is any clinical evidence of obstruction; the bowels may still act normally, or diarrhœa may be present, and an opaque meal may pass through the whole colon without delay. This is probably due to the occurrence of a spasmodic contraction of the bowel, which occurs at the seat of obstruction as soon as the enema reaches and distends the part immediately below it. An opaque meal or, more readily, an opaque enema may show the presence of a filling defect in the colon caused by a growth. It also shows the exact length and position of strictures due to other causes, and it is the only way in which the presence of diverticula can be definitely determined.

EXAMINATION OF FÆCES

The consistence, smell, colour and reaction of the stools should be noted, abnormal acidity indicating excessive fermentation and abnormal alkalinity excessive putrefaction. The presence of mucus, blood or pus indicates organic disease; if the two former are intimately mixed with the stools, the blood being only present in an altered condition recognisable by chemical means, but not by the microscope, they probably come from the small intestine: the larger the fragments of mucus and the brighter the colour of the blood the lower is their source. The presence of pus always indicates disease of the colon, as any produced in the small intestines is digested. The presence of excess of undigested meat or vegetable food should be noted.

Pale, bulky stools generally indicate the presence of excess of fat. It is important to ascertain whether this is chiefly in the form of neutral fat, as in pancreatic insufficiency, or in the form of fatty acids and soaps, as in deficient absorption caused by obstruction of the lacteals with normal pancreatic digestion. This can generally be decided by microscopical examination, but in doubtful cases an accurate chemical analysis should be undertaken.

Microscopic examination may reveal the presence of blood corpuscles, pus, amœbæ or their cysts and the ova of intestinal worms in addition to fragments of animal and vegetable food which have escaped digestion.

Occult blood.—When blood is swallowed or is derived from an ulcer or growth in the stomach or an ulcer in the duodenum, it is evacuated in the stools partly as acid hæmatin and partly as hæmatoporphyrin. Both also appear in the stools when the blood originates in the colon unless diarrhœa is present, when the blood does not remain in the bowel long enough for the former to be converted into the latter. The chemical tests for "occult blood"—traces of blood insufficient to produce any change in the appearance of the fæces—depend upon the conversion of a substance with little or no colour, such as guaiac or benzidine, into a coloured substance when oxidised by hydrogen peroxide in the presence of a carrier, such as hæmatin. Hæmatoporphyrin, which contains no iron, does not give the reaction. The spectroscopic examination of the stools should also be used, as traces of hæmatoporphyrin, which is occasionally present in the absence of acid hæmatin, would otherwise escape recognition. Moreover, a positive spectroscopic finding is valuable confirmation of a positive chemical

reaction, as, although it is much less sensitive, there is less chance of error.

Before examining the stools, the patient is given a hæmoglobin-free diet. Chlorophyll should also be excluded, as it gives a feebly positive guaiac reaction and its many-banded spectrum may cause confusion in the spectroscopic examination. A charcoal biscuit is given with the first meal on the restricted diet, and the first and subsequent stools passed when the fæces are no longer blackened by the charcoal are examined. For the guaiac and spectroscopic tests a small amount of fæces is macerated with glacial acetic acid into a thin paste. An equal quantity of ether is then added to extract the pigment; the ethereal extract is poured off, some being kept for the spectroscopic examination. Two or three drops of tincture of guaiac are added to the remainder; a small quantity of ozonic alcohol is then poured in, and a change of colour is looked for at the junction of the two fluids. A "positive reaction" is one in which a deep blue colour rapidly appears; a "feebly positive" reaction is one in which the colour is faint purple, bluish, or greenish.

A positive guaiac reaction signifies the presence of occult blood, and a positive spectroscopic examination shows that it is present in fairly considerable quantities. A negative guaiac reaction proves the absence of occult blood, except occasionally at the end of a period of hæmorrhage, when the spectroscopic test may alone be positive, as the traces of blood still present may then be completely converted into hæmatoporphyrin, which gives a characteristic spectrum, but does not give the chemical reactions.

In the absence of hæmorrhoids and of bleeding from the mouth, throat and nose, the presence of occult blood is strong evidence that ulceration is present in the stomach or intestines. When symptoms pointing to gastric or duodenal ulcer and gastric carcinoma are absent, a suspicion of cancer of the intestine receives important confirmation.

A bacteriological examination of the stools should always be made in cases of diarrhœa, with or without colitis. The presence of a relative excess of streptococci, or the presence of abnormal varieties of the *B. coli*, or of enteric, parenteric, dysentery and tubercle bacilli, may be discovered. If a sigmoidoscopic examination is made, a swab should be taken for bacteriological examination directly from the mucous membrane; if any mucus is seen, this should be taken for the purpose. In doubtful cases the agglutinating power of the patient's blood for the bacteria isolated from the stools should be tested.

SIGMOIDOSCOPIC EXAMINATION

In all cases in which there is any possibility of organic disease of the pelvic colon or rectum a sigmoidoscope should be passed after a preliminary digital examination. No special preparation is required, but the patient should endeavour to get his bowels emptied as completely as possible before the evacuation without the aid of aperients or enemata. The sigmoidoscope is passed most satisfactorily without an anæsthetic in the knee-elbow position. If digital examination is painful owing to inflammation of the anal canal, a cocaine semple should be applied in order to anæsthetise it before the sigmoidoscope is passed.

FUNCTIONAL DISORDERS OF THE INTESTINES

CONSTIPATION

Definition.—Constipation may be defined as a condition in which none of the residue of the first meal taken after defæcation is excreted within the next 48 hours.

Ætiology and Pathology.—Constipation may be due to (1) the passage through the colon being delayed, whilst defæcation is normal—*colic constipation*; (2) the evacuation from the pelvic colon being inadequately performed, whilst the passage through the colon is normal—*dyschezia*; and (3) insufficient formation of fæces.

1. *Colic constipation.*—Delay in the passage of fæces through the intestines is due to their motor activity being deficient, or to the force required to carry the fæces to the pelvic colon being excessive. The motor activity of the colon may be deficient owing to weakness of its musculature, deficient reflex activity, inhibition, or uncontrolled and irregular action. Weakness of the musculature may be due to congenital hypoplasia, which is the cause of the constitutional constipation from which several members of a family may suffer; acquired hypoplasia, which is the cause of senile constipation and the constipation which may follow such local diseases as dysentery; and functional insufficiency without structural change, as in all conditions leading to malnutrition and general ill-health. The reflexes which maintain intestinal activity may be deficient owing to the stimulation being too weak on account of want of exercise or lack of mechanical and chemical stimulants in the food, or to deficiency in hormones, particularly in hypothyroidism. They are also deficient when the excitability of the mucous membrane is impaired as a result of long-continued irritation by purgatives. The inhibitory sympathetic nerves may be stimulated centrally by depressing emotions, and reflexly in painful diseases and injuries of any part of the body, but particularly of the abdominal and pelvic viscera.

Constipation may result from painful spasm, induced reflexly by the presence of an irritant in the colon of a patient with an abnormally excitable nervous system, due most frequently to neurasthenia (*enterospasm, spastic constipation*). The irritant which gives rise to the exaggerated reflexes is in most cases hard fæces, which have been retained as a result of constipation, caused by insufficient and unsuitable food and too little exercise. The reflex may also be excited by disease in other parts of the abdomen, especially chronic appendicitis. Similar spasmodic contractions of the intestines occur as a result of excessive smoking, and in lead poisoning.

The work to be done by the intestinal musculature is excessive when the consistence of the fæces offers more than the normal degree of resistance owing to insufficient consumption of water or its excessive loss in the urine or sweat, and when there is a diminution in the intestinal lumen owing to organic stricture or pressure exerted from without.

2. *Dyschezia.*—Dyschezia is due to a want of proper proportion between the power of expelling the fæces from the pelvic colon and rectum, and the force required to do this completely. It may therefore be due to inefficient defæcation, or to an obstacle to efficient defæcation, such as abnormally

hard and bulky *faeces* and strictures of the rectum and anal canal. Dyschezia due to inefficient defæcation is the most common cause of severe constipation, and is generally of nervous origin. It often originates in neglect to respond to the call to defæcate owing to laziness, insanitary conditions of the w.c., or false modesty. The rectum gradually dilates so that an increasing quantity of *faeces* is needed to produce the adequate internal pressure required to give the sensation of fullness, which is the natural call to defæcation. Finally the sensation is lost completely. But the patient is still capable of emptying his rectum if he tries. He has, however, by now often convinced himself that he cannot get his bowels to open unless he takes enemata or such enormous doses of aperients that the fluid *faeces* practically act as enemata. He thus suggests to himself that his rectum is powerless to act by itself, true hysterical dyschezia being produced.

Dyschezia may be due to various other causes, such as weakness of the voluntary muscles of defæcation, the assumption of an unsuitable position during defæcation, and voluntary inhibition from fear of pain in diseases of the anus and the neighbouring organs. But whatever the primary cause, the final result is the same. The incomplete evacuation of the rectum results in an accumulation of *faeces* and consequent atony and dilatation of the rectum.

Congenital deficiency of the muscle-sense of the rectum is the cause of the dyschezia of infants, in whom the slight additional distension produced by the introduction of a finger or a piece of soap into the rectum results in an adequate stimulus. In the majority of cases the muscle-sense develops when the infant grows older; but this is occasionally the starting-point of dyschezia which lasts through life. The rectal muscle-sense is abolished or defective in diseases of the spinal cord, in which the defæcation centre itself or the fibres connecting it with the brain are involved.

3. The third great class of constipation is due to the quantity of *faeces* formed being insufficient to produce an adequate stimulus in the pelvic colon and rectum, and to a less extent in the rest of the colon. The insufficient bulk of *faeces* is due to an inadequate quantity of food residue reaching the colon as a result of anorexia or of œsophageal or pyloric obstruction, or to excessive digestion of food, the result of a "greedy bowel."

Symptoms.—Many people regard themselves as ill if they do not have one action of the bowels a day; but this is really nothing more than a question of convenience, being found to suit the habits and diet of the majority of civilised people. Perfect health may be maintained by individuals who defæcate regularly two or three times a day, and by others who obtain an evacuation once in 2, 3 or more days. The latter, so long as defæcation, when it does occur, is complete, can no more be regarded as diseased than those otherwise normal people, whose hearts beat only forty or fifty times a minute. The majority, however, although they may suffer no inconvenience for a considerable time, finally develop symptoms due to fecal accumulation, gradually increasing quantities of *faeces* being retained. For practical purposes, therefore, an individual may be considered constipated if his bowels are not opened at least once in every 48 hours. A less frequently recognised variety of constipation is that in which insufficient *faeces* are excreted, although the bowels may be opened every day—a condition analogous to retention of urine with overflow.

It is important to distinguish the symptoms of constipation from those of the conditions which may give rise to it. There is no doubt that neurasthenia, insanity, epilepsy, asthma, nephritis, diabetes, painful pelvic disorders and many other diseases may be greatly aggravated by constipation. Apart from these conditions, headache, mental and physical fatigue, vertigo, anorexia, and pigmentation of the skin may result directly from intestinal intoxication and the reflex effects of constipation. Toxic symptoms rarely develop unless stasis occurs in the cæcum and ascending colon, in which the fæces are still soft. Reflex symptoms, on the other hand, occur chiefly in dyschezia as a result of the pressure produced by hard fæces. The latter differ from the former by their almost instantaneous disappearance on defæcation. Fæcal retention is a common cause of intestinal flatulence and colic. In rare cases a fæcal tumour and fæcal obstruction occur. A fæcal accumulation in the rectum may cause hæmorrhoids, pruritus ani, catarrhal and ulcerative proctitis and neuralgic pains in the back, down the legs, and in the female pelvic organs. Hard fæces make defæcation painful, and their passage may give rise to anal ulcers.

Diagnosis.—It is comparatively rare for a patient to consult a doctor on account of constipation without having already attempted to cure himself with aperients. But no accurate diagnosis can be made until it has been ascertained whether he is actually constipated at all. The symptoms generally ascribed to auto-intoxication caused by intestinal stasis are often really produced by purgatives, which lead to the absorption of excess of toxic material by hastening the half-digested contents of the small intestine into the cæcum, where fermentation and putrefaction are consequently increased, and by causing the contents of the transverse, descending and pelvic colon to be fluid instead of solid, so that absorption of toxins continues throughout the length of the bowel instead of in the cæcum and ascending colon alone. In spite of his probable protests the patient is instructed to see what happens if no drugs are taken for 3 days, an effort being made to open the bowels each morning. In most cases he loses his abdominal pain and his so-called toxic symptoms. The bowels are often opened daily, in which case a diagnosis of *hysterical pseudo-constipation* can be made—hysterical because the patient had suggested to himself, as a result of faulty education combined with the reading of pernicious advertisements, that he was constipated and required aperients to keep himself well, whereas a little psychotherapy, in the form of explanation of the physiology of his bowels and the origin of his symptoms, and persuasion to try to open his bowels each morning without artificial help, result in a cure. In many cases, however, the patient does not succeed in opening his bowels, although he may feel more comfortable than when he was taking drugs. A second abdominal and rectal examination should now be made. If no sign of organic disease is present, and the rectum is found to be filled with fæces, dyschezia can be diagnosed. In spite of this the patient has no desire to open his bowels; a normal individual would feel an urgent call to defæcation under such conditions, but the rectum has been allowed to dilate by being constantly full of fæces and the call to defæcation is no longer felt.

In severe cases it is advisable to examine the intestinal functions with the X-rays, a barium meal being given after the patient has discontinued taking aperients (Fig. 21). Ileal stasis should only be diagnosed if no trace of barium

has reached the cæcum 6 hours after the opaque meal, or if a considerable quantity of barium-containing chyme is still in the end of the ileum 10 hours after the meal. If most of the barium is still in the cæcum and ascending colon at the end of 24 hours, stasis is present, even if a little has passed to the more distant parts of the colon; but a faint shadow of the cæcum is often visible in normal individuals even 3 days after the meal. If the splenic flexure was reached in 24 hours, and the greater part of the barium is in the transverse colon at the end of 48 hours, there must be stasis in this part of the bowel.

Treatment.—Under no circumstances should the patient fail to make an effort to open his bowels after breakfast, even if he feels no desire to do so, and a call to defæcation felt at any other hour in the day should be obeyed at once, at whatever inconvenient time it may occur. Sufficient time should always be spent over the act of defæcation, and it is often advisable to pay two visits to the closet at short intervals. In order to prevent the temptation to hurry over defæcation the closet should be clean, devoid of smell, and properly warmed in winter. In dyschezia a footstool 9 inches lower than

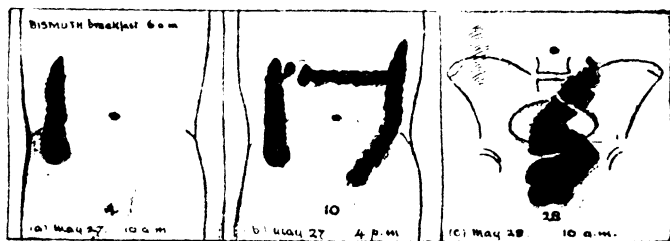

FIG. 21. —Dyschezia in a girl of 17, whose bowels had not been opened for 5 weeks when admitted to hospital. (First case of constipation ever examined with X-rays: February 1907.)

the seat should be provided, and in severe cases the patient should crouch over a bed-pan placed on the floor. In many cases of dyschezia no treatment is required beyond explaining to the patient the nature and cause of his condition, and persuading him to give up aperients and to make an effort to empty his rectum, which he must realise is quite capable of doing its work.

It is most important to see that sufficient food is taken, as constipation is often as much due to its insufficient quantity as to its unsuitable quality. The diet should contain an increased proportion of vegetable foods, especially those which contain much cellulose, organic acids and sugar. Fresh or dried fruit should be taken three times a day, and green vegetables or salad should be eaten at lunch and dinner. Stewed prunes taken at breakfast, the number being regulated according to the degree of constipation, are especially valuable. Porridge and cream and wholemeal brown bread are also useful. Care should be taken that sufficient fluid is drunk; a glass of cold water taken on rising in the morning often helps the bowels to act after breakfast.

The majority of cases of constipation can be cured without drugs if proper treatment is instituted at a sufficiently early stage. In dyschezia

purgatives are either absolutely useless or they only have an effect when fluid stools are produced, a considerable quantity of fluid and nutritive material being thereby wasted. In the treatment of diseases which are aggravated by coexisting constipation, purgatives should be regularly given. They are also useful for making the stools soft when defæcation is painful as a result of inflamed hæmorrhoids or anal ulcer and in diseases of the pelvic organs, and when straining at stool is accompanied by danger, as in patients liable to cerebral hæmorrhage. In those cases of constipation due to other causes, in which non-medical treatment proves insufficient, purgatives must also be used, but an effort should be made to dispense with drugs at the earliest possible moment. The stool produced by an aperient should be normal in size and consistence; the dose should be so regulated that one stool is passed every day and the desire to defæcate is felt immediately after breakfast. An infusion of senna pods in cold water is particularly useful, as the dose can be regulated from day to day by the patient; an attempt should be made at intervals to reduce the number used by one at a time, until finally none may be required. The aperient should cause no pain or discomfort, and should not irritate the intestinal mucous membrane sufficiently to produce any inflammatory change. If it is probable that the purgative will be required permanently, one such as aloes, cascara or senna should be chosen, which is likely to maintain its good effect without any increase in the dose being required.

In constipation due to a greedy colon the bulk of the fæces must be increased by the administration of some unirritating substance, such as liquid paraffin or agar-agar, which passes through the intestines without undergoing decomposition or absorption. Liquid paraffin is particularly valuable when the fæces are hard and dry; it is therefore useful in other varieties of constipation besides that due to a greedy colon, as fæces always become hard and dry as a result of their abnormal retention in the bowel. In dyschezia also the soft stools which result from its use are expelled with less difficulty than ordinary fæces. From 1 drachm to 1 ounce should be taken immediately after meals two or three times a day.

The majority of cases of moderately severe constipation are more or less cumulative, excess of fæces being always present in the large intestines. It is therefore necessary that the colon should be completely evacuated before other methods of treatment are adopted. This can best be done by washing the colon out with a pint and a half or two pints of warm water run into it from a douche can at low pressure through a tube inserted just beyond the anal canal. In rare instances the rectum can only be emptied by means of the finger.

It is essential in treating dyschezia to keep the rectum and pelvic colon empty, so that they may in time regain their normal tone and contractile power. This can be accomplished by the use of enemata of water or glycerine every morning, but only if a prolonged attempt to defæcate naturally has proved unsuccessful. The bulk of the water enemata and the strength of the glycerine enemata should be gradually reduced. As a rule the tone and contractile power slowly return and a cure finally results.

Regular exercise in the open air is one of the most important means of preventing constipation, especially in individuals who follow a sedentary occupation. When any of the voluntary muscles of defæcation are weak, considerable benefit can be gained by the performance of Swedish exercises

every morning and evening. Special attention should be devoted to the levator ani muscles, especially in women in whom the pelvic floor has been injured during parturition, and in cases in which there is any tendency to prolapse on straining at stool (*vide* p. 676). If constipation is due to want of activity of the intestinal musculature, the condition of the latter may be improved by deep abdominal massage. This should be directed particularly to the part of the colon in which the X-rays have shown that stasis occurs. Its efficacy is greatly increased if the first treatment is given during an X-ray examination, as the masseur can then see the exact position of the colon and can find what manipulations have most effect upon it.

DIARRHOEA

Definition.—Diarrhœa is a condition in which fluid stools are passed. Defecation generally occurs several times in the day, but mere frequency of defecation is not diarrhœa, for this may even be associated with constipation. The bulk of fæces excreted in 24 hours is generally excessive, but this again is not an essential factor, as excessive fæces are occasionally formed when the passage through the alimentary canal is not abnormally rapid. The one essential factor in diarrhœa is the abnormally rapid passage of the food residue through the alimentary canal; diarrhœa is therefore the direct counterpart of the form of constipation which I have called colic constipation.

Ætiology.—1. EXCESSIVE STIMULATION OF MOTOR ACTIVITY.—The most common cause of diarrhœa is the presence in the food of excess of the mechanical and chemical stimulants of intestinal activity. Thus over-indulgence in green vegetables, salads, and still more frequently fruit, is a familiar cause. Chemical irritants may also be swallowed in decomposing food, as in some cases of fish and meat poisoning, but food more often causes diarrhœa by giving rise to a bacterial infection of the intestine than by the introduction of pre-formed toxins. Diarrhœa very frequently results from the habit of taking aperients, either in excess of what is required for the correction of chronic constipation, or even when the bowels left to themselves would act quite normally. Thus many of the symptoms often ascribed to constipation are really due to the diarrhœa caused by purgatives, as it results in the absorption of excess of poisons from the too fluid fæces.

Chronic diarrhœa is most commonly due to infection with some pathogenic organism which gains access to the intestines in contaminated food or water. Acute diarrhœa is most frequently the immediate result, but it often becomes chronic, or it disappears temporarily and is followed by recurrent acute attacks, which may be separated by periods of constipation. In some cases the infection is derived from a septic focus in the mouth, nose or pharynx, and in rare cases chronic appendicitis is the source of a chronic infection of the colon. Some *infective bacteria*, such as the *paratyphic* group, act chiefly on carbohydrates and may lead to excessive fermentation. Others, such as streptococci and various anaerobes, act on proteins and lead to putrefactive diarrhœa. Intestinal carbohydrate dyspepsia (*vide* p. 582) only rarely gives rise to diarrhœa in spite of the excessive growth of enterococci, but deficient digestion of proteins, either resulting from gastric or pancreatic insufficiency, may lead to a non-infective putrefactive diarrhœa. Deficient digestion of

fat owing to pancreatic insufficiency or obstruction to the outflow of pancreatic juice in obstructive jaundice occasionally leads to *fatty diarrhœa*, which must be distinguished from *chylous diarrhœa* in which excess of fatty acids and soaps are passed owing to obstruction of the lacteals by disease of the mesenteric glands.

Diarrhœa is often gastric in origin. This *gastrogenous diarrhœa* may occur when the gastric juice is deficient or absent. An abnormal number of organisms reaches the intestines in these circumstances, as the partial protection afforded by the bactericidal action of the hydrochloric acid in the stomach is lost. As the connective tissue of meat and the cellulose of vegetables are normally softened by the hydrochloric acid of the gastric juice, undigested lumps of meat and fragments of vegetable leave the stomach and pass through the small intestine to the colon, where they are liable to undergo bacterial decomposition. The irritation of the mucous membrane of the intestines by the insufficiently divided fragments of food and by the products of bacterial decomposition leads to diarrhœa, which may become aggravated by secondary entero-colitis if the irritation is sufficiently intense or prolonged. Similar gastrogenous diarrhœa may occur after the performance of a gastro-jejunostomy, the food leaving the stomach with such rapidity that the intestines are overwhelmed with undigested and irritating food.

Lastly, chemical stimulants to intestinal activity may be produced in the body and excreted into the colon; this is the cause of diarrhœa in uræmia, Graves' disease and septicæmia.

2. OVER-EXCITABILITY OF THE NEURO-MUSCULAR MECHANISM WHICH CONTROLS THE INTESTINAL MOVEMENTS.—(a) *Lienteric or post-prandial diarrhœa*.—Under normal conditions the entry of food into the empty stomach gives rise to a *gastro-colic reflex*, which is the chief stimulus to the movements of the colon. In most individuals this is only followed by defæcation after breakfast, as the pelvic colon is then full, and the sudden passage of fæces from it into the rectum gives rise to the call to defæcation. Sometimes the gastro-colic reflex is abnormally active. This may only manifest itself after breakfast; a formed stool is passed first, but in the course of the next half-hour or hour one or more loose stools are passed in addition. In severer cases the bowels are also opened after dinner and less frequently after lunch, the stools again being often soft or fluid, in contrast with the first stool passed in the day, which is generally solid.

(b) *Nervous diarrhœa*.—It is not uncommon for a fright to result in the immediate passage of a semi-fluid stool. In some patients, who are often not otherwise neurotic, attacks of diarrhœa occur whenever they are in any place where it would be awkward for them to relieve themselves: when this has once happened, it is likely to recur under similar circumstances, largely owing to fear that it will do so. Lienteric and nervous diarrhœa are often associated together, a patient suffering from the former being particularly likely to feel an urgent desire to defæcate if he is at a dinner party or in a railway carriage without a lavatory.

Diarrhœa, whatever its cause may be, tends to be worse after meals, especially breakfast, and it is occasionally also influenced by nervousness; it is important, therefore, to exclude some other primary cause before diagnosing a case as one of pure lienteric or pure nervous diarrhœa.

(c) *Irritable colon*.—When the mucous membrane of the colon is in-

flamed or ulcerated, any mechanical or chemical stimulant is likely to produce an excessive reflex response, so that the diarrhœa which is probably already present is aggravated. Apart from this, many people, who have lived in the tropics and have suffered there from dysentery, or diarrhœa due to some less defined cause, continue to be liable to diarrhœa for many years after their return to a temperate climate.

Symptoms.—The chief and often the only symptom of diarrhœa is the abnormally frequent passage of abnormal stools. In severe cases of diarrhœa discomfort or even pain is felt over the whole of the lower part of the abdomen for a short time before the bowels are opened. It may be followed by a sensation of soreness, but the abdomen is neither tender nor rigid, and warm applications generally relieve it. Occasionally severe colic occurs, which may be temporarily relieved each time the bowels are opened or flatus is passed. The passage of a large and watery stool is often followed by a feeling of exhaustion and faintness, which may be accompanied by sweating and coldness of the extremities and occasionally even by syncope.

In severe cases of acute diarrhœa and in persistent cases of chronic diarrhœa the nutrition suffers and the patient loses weight; sometimes an extreme degree of emaciation results. When the diarrhœa is associated with abnormal bacterial activity in the intestines, especially if this is of the putrefactive type, more or less severe symptoms of intestinal intoxication, indistinguishable from those which are sometimes associated with severe intestinal stasis, may develop.

Diagnosis.—When a patient complains of diarrhœa, it is first necessary to ascertain whether the passage of fæces through the intestines is really taking place with abnormal rapidity. Many people think that frequent defæcation, particularly if the stools are in part fluid, is sufficient evidence that diarrhœa is present, whereas this is by no means necessarily the case. The stools of every patient supposed to be suffering from diarrhœa should be examined; if they are of a uniform semi-solid or fluid consistence, true diarrhœa is probably present, whereas numerous stools, if they are small and solid, and fluid stools containing small solid fragments suggest a diagnosis of *pseudo-diarrhœa*. In a doubtful case 2 or 3 charcoal lozenges should be given with some food immediately after the bowels have been opened in the morning; each stool is now examined, and the time which elapses before black fæces are passed is noted. If charcoal is seen in the stools within 12 hours true diarrhœa is present; if in less than 4 hours, the small intestine must be involved as well as the colon. If no charcoal appears within 48 hours, constipation and not diarrhœa is present. A series of X-ray examinations after a barium meal affords a more accurate method of determining the rate of passage through the alimentary canal, and it has the advantage of showing in what part of the bowel the rate is excessive.

The most common cause of *pseudo-diarrhœa* is dyschezia: although the rectum is never properly emptied, the patient may feel a constant desire to open his bowels, and as a result of his efforts a very small quantity of hard fæces may be passed. If, as is often the case, the constant presence of fæces in the rectum gives rise to catarrhal proctitis, more or less mucus is passed in addition. In slight cases there may be nothing more than a thin layer of mucus over the hard lumps of fæces; in severer cases a larger quantity of fluid mucus, which is often stained brown, is passed either alone or with hard

particles of *fæces*. In all such cases the discovery of solid *fæces* in the rectum, immediately after the bowels have been opened, should remove any further doubt as to the diagnosis. A growth of the rectum or pelvic colon and less frequently a growth in other parts of the colon, though rarely on the proximal side of the splenic flexure, may lead to pseudo-diarrhoea, *fæces* being retained above the growth, whilst the serous and often blood-stained exudation from its surface, and mucus produced by the irritant action of the exudation on the mucous membrane below it, are passed at more or less frequent intervals, so that the patient regards himself as suffering from diarrhoea. The character of the stool should at once make it obvious that further examinations by means of the sigmoidoscope and with the X-rays after a barium meal and a barium enema are required, even if nothing abnormal is felt in the abdomen or on rectal examination.

When it is known that genuine diarrhoea is present, it is next necessary to determine whether it is due to a functional or an organic cause. The history is often a great help; *lionteric* or nervous diarrhoea dating from childhood, especially if other members of the patient's family are similarly affected, is almost certainly either functional or due to constitutional *achylia gastrica*.

A very acute onset suggests that the cause is some toxic or infective agent, whereas a more gradual onset of chronic diarrhoea in a middle-aged individual, who has hitherto been regular or constipated, suggests the presence of a growth. A careful abdominal and rectal examination should be made in every case; the former may reveal the presence of a tumour or an abnormally dilated or contracted condition of the colon; by means of the latter the existence of ulcerative colitis may be recognised, as well as the presence of a growth in the rectum or pelvic colon. In doubtful cases a sigmoidoscopic examination should also be made before deciding that the diarrhoea is functional in origin, as the mucous membrane of the accessible part of the colon is almost always involved when diarrhoea is due to some form of colitis.

The examination of the stools is of the greatest importance, as it gives valuable indications for treatment as well as helping in diagnosis. The presence of mucus, blood or pus indicates either some form of colitis or a growth. Excess of vegetable residue is often recognisable in fermentative diarrhoea and of animal residue in putrefactive diarrhoea, when these are due to deficient digestion of carbohydrates or proteins respectively. The *fæces* are often frothy, and have an acid smell and reaction when fermentation is excessive; they may be alkaline and have a putrefactive odour when excessive putrefaction is present.

The stools passed when fat is insufficiently digested or absorbed are easily recognised by their pale colour and enormous bulk. If the excess is in the form of neutral fat, the stools are oily (*fatty diarrhoea*), and pancreatic insufficiency can be diagnosed; on giving a fat-free diet, excess of striated meat fibres and vegetable residue is still present. This condition is, however, very rare in the absence of jaundice indicating obstruction of the common bile-duct. More frequently most of the fat is present as fatty acid and soaps (*chylous diarrhoea*), showing that pancreatic digestion is normal, but that absorption is deficient owing to obstruction of the lacteals by tuberculous, simple inflammatory, or secondary malignant disease of the mesenteric glands.

In most cases the stools become perfectly normal on a fat-free diet, the digestion of meat and vegetable food being unaffected. Almost all the calcium in the food combines with fatty acid to form calcium soap in this condition; the blood calcium is consequently diminished, and tetany may result. In children growth is greatly impaired, and the long bones are soft and may bend, with the production of various deformities.

A bacteriological examination should always be made, in the hope that the nature of any infection which is present may be discovered.

Prognosis.—If thorough treatment is instituted from the onset, the prognosis of diarrhoea is good, unless it is due to some serious organic disease. If, however, it is neglected, strict treatment must be continued for a prolonged period in order to be successful. This is particularly the case when the diarrhoea is infective in origin.

The tendency to lenteric and nervous diarrhoea often remains throughout life, though considerable improvement and even a cure can result from treatment. Unlike other forms of diarrhoea, they rarely affect the general health, and are chiefly troublesome on account of the inconvenience they cause.

Treatment.—*Acute Diarrhoea.*—If a patient is seen within 12 hours of the onset of an attack of acute diarrhoea due to food poisoning, he should be given from $\frac{1}{2}$ to 1 ounce of castor oil to clear the irritant material out of the small as well as the large intestine, unless the diarrhoea is so severe that it appears probable that this has already occurred. No food should be given for 24 hours, or even longer in severe cases, but the patient may drink as much water as he likes. Arrowroot made with water should then be given, but nothing else until the diarrhoea has ceased. Milk, junket, bread and butter, and milk puddings are next allowed, after which a gradual return should be made to an ordinary diet, the speed with which this is done depending on the severity of the case. The only drugs which are of real use in acute diarrhoea are opium and its alkaloids. If the diarrhoea shows no signs of abating after 24 hours, some preparation of opium, morphine or codeine should be given, the dose being regulated according to the severity of the diarrhoea and the general condition of the patient, but sufficient must be given to stop the diarrhoea in 48 hours.

Chronic Diarrhoea.—In all cases of chronic diarrhoea recovery occurs most rapidly if the patient remains in bed during the first few days of treatment. In many instances diarrhoea, which may have been present for months, disappears in a few days and the patient may even become constipated. Unless, however, other treatment is instituted, the diarrhoea is very likely to return as soon as he gets up again. As the improvement which results from staying in bed is due in part to the rest and in part to warmth, it is important for the patient to avoid over-exertion and to keep his abdomen warm by means of a woollen binder for a considerable period after the symptoms have disappeared. Exposure to cold should be avoided as much as possible, and if the patient feels chilled at any time he should have a hot bath and go to bed at once; by this means he is likely to prevent a recurrence. Patients who have recently suffered from chronic diarrhoea should never go to the tropics, and they should even avoid visiting the southern parts of Europe, as a slight intestinal attack from bad food is likely to have much more serious results with them than in an individual who has not before suffered from any intestinal disorder.

The successful treatment of chronic diarrhœa depends upon the recognition of its cause. The treatment of diarrhœa which is secondary to organic disease of the intestines, such as colitis and cancer, is considered elsewhere.

1. **EXCESSIVE STIMULATION OF THE INTESTINAL MOVEMENTS.**—Whatever the actual cause of the diarrhœa it is important to avoid anything which could produce mechanical irritation of the colon. The food should be thoroughly chewed, and anything, such as new bread, cheese and tough meat, which is difficult to break up completely, should not be eaten. The patient must avoid all raw vegetables in salads and pickles, and cooked green vegetables are only allowed as purées. The pips and skins of fruit, whether raw, cooked or in jam, and currants, raisins and lemon peel in puddings and cakes must be avoided.

In *fermentative diarrhœa* all food containing starch and cellulose should at first be completely excluded from the diet. When the diarrhœa has stopped, cellulose-free starch, such as arrowroot, may be given, but no potatoes, white bread or rice for 3 or 4 weeks, and no vegetables containing a greater quantity of cellulose until still later. A lacto-vegetarian diet is most suitable for *putrefactive diarrhœa*. Capsules of *B. acidophilus* should be given three times a day between meals. No meat should be allowed until the diarrhœa has ceased for 4 weeks, and high game or over-ripe cheese should not be eaten for many months.

Fatty and chylous diarrhœa stops at once on a fat-free diet. In severe cases, in which obstruction of the lacteals is present, it may be necessary for the patient to continue with this diet for the rest of his life.

Gastrogenous diarrhœa rapidly improves on the diet already described as suitable for putrefactive diarrhœa, but a relapse is certain to follow a return to an ordinary diet unless hydrochloric acid is given (see Achylia Gastrica).

2. **NERVOUS AND LENTERIC DIARRHŒA.**—Nervous diarrhœa is often completely uninfluenced by diet, but drugs, which diminish the activity of the gastro-colic reflex either peripherally or centrally, are very effective. A mixture containing 5 grains of potassium bromide and 5 minims of tincture of belladonna taken immediately before meals is all that is required in mild cases; in severer cases a small dose of codeine should be added. The exact dose of each drug must be varied to suit each patient, as different individuals react very differently to these drugs, especially to belladonna. When the diarrhœa has been completely controlled, the quantity of each drug should be gradually reduced; then the doses before lunch and dinner and finally that before breakfast can be discontinued. In most cases it is still advisable to allow the patient to have the medicine or a pill containing belladonna and codeine always with him, so that he can take a dose before going to a dinner party or any other occasion, when he fears that he will have diarrhœa. He soon learns to trust so thoroughly in his pill that it probably acts more by suggestion than in any other way, and the dose can accordingly be progressively reduced until it is infinitesimal.

As in many cases of diarrhœa due to other causes the bowels act most frequently after meals, the treatment just described is often of use in conjunction with that required for the primary condition.

ARTHUR F. HURST.

EPIDEMIC DIARRHŒA IN CHILDREN

Synonyms.—Summer Diarrhœa ; Infective or Infectious Diarrhœa ; Acute Gastro-Intestinal Infection ; Acute Ileo-Colitis ; Cholera Infantum.

The form of diarrhœa here spoken of is one of the chief scourges of infant life, though certainly much less common than formerly. It prevails epidemically in the third quarter of the year, although sporadic cases may be met with at any time, and in hot seasons may become widespread, especially in large towns. It chiefly affects children below the age of 5, but is most fatal in the first year. Boys are more susceptible than girls.

Ætiology.—It is generally agreed that the disease is caused by infection with micro-organisms ; but in spite of much research the bacteriology is by no means clear. It would appear that all cases are not due to the same organism, and amongst those which have been isolated from the stools in different epidemics are the *Proteus vulgaris*, the *Bacillus coli*, streptococci, the *B. enteritidis*, Morgan's bacillus, and various strains of dysentery bacilli. Any of these, or several of them in combination, seem to be capable of inducing the affection, given the predisposing conditions. Of the latter by far the most important is a sustained high temperature (60° F.) of the air and, particularly, of the soil. As was pointed out long ago by Ballard, it is when the temperature recorded by the four-foot earth thermometer reaches 56° F. that cases begin to occur. Such a temperature probably provides the conditions necessary for the growth of the infecting organism.

Next in importance as an ætiological factor must be put the influence of unhygienic surroundings, such as dirt, overcrowding, a contaminated milk supply, and want of cleanliness in feeding utensils. The infection is probably often conveyed by dust, and flies may act as carriers.

Any digestive derangement in the child may predispose to infection, and bottle-fed infants are specially liable. The disease appears to be to some degree contagious, and if introduced into a ward is apt to spread to unaffected infants. The influence of age and sex have already been referred to.

Pathology.—The changes found after death may be surprisingly slight, considering the severity of the disease, and vary materially in different cases and epidemics. As a rule the mucous membrane of the stomach and intestines is in a condition of "mucous catarrh." There may also be areas of congestion, with here and there small petechial hæmorrhages. The lymphoid tissue of the alimentary canal is often swollen, and in severe and protracted cases the solitary follicles in the colon and lower ileum may exhibit superficial ulceration.

Other organs, such as the liver and kidneys, show fatty or parenchymatous degeneration, whilst the lungs are often congested and œdematous, with, in protracted cases, patches of broncho-pneumonia in the lower lobes.

Symptoms.—The clinical picture is often very complicated, and if it is to be understood it is essential to realise that the disease is a general infection and not merely a disorder of the alimentary canal. The supervention of secondary "food intoxications," acidosis or nephritis, with their own clinical manifestations, tend still further to perplex the observer and make it impossible for him to decide to what extent the symptoms are due to the primary infection or to these secondary developments

The disease may start insidiously, with a gradually increasing diarrhoea; or the onset may be abrupt, with a rapid rise of temperature and early prostration. The diarrhoea is not necessarily a pronounced feature, and the worst cases are often those with fewest stools. The character of the motions varies; but in the early stage they are usually green, slimy and ill-digested, becoming dark and watery later. In the choleraic cases they are of the profuse "rice-water" type. When the colon is affected, visible mucus and blood may be passed with much straining. The discharges are usually attended by colicky pain and the passage of flatus. Vomiting is generally present at the onset, but varies greatly in amount. The temperature is always elevated at some period of the disease, but the height, duration and course of the pyrexia are very inconstant. Hyperpyrexia may supervene towards the close in fatal cases. Prostration and circulatory failure are early features, and are shown by depression of the fontanelle, pallor, pinched features, an inelastic skin and coldness of the extremities. Where "intoxication" is a factor, consciousness becomes impaired, and the infant passes into a state of stupor, with intervals of restlessness, which may result in complete coma, sometimes terminating in convulsions. If acidosis is present, the respiration may show the characters of "air-hunger."

The urine is scanty, highly acid and contains a little albumin and a few hyaline casts. Acetone bodies may be present.

Course.—The course of the disease varies greatly. In the severest cases, especially those of the choleraic type, death may ensue within a few hours of the first onset of symptoms. In the milder forms the acute symptoms last for 2 or 3 days, and then gradually the prostration passes off and the stools assume a normal character. Only too often, however, the improvement is but partial, and the child lapses into a marasmic condition, with continued looseness of the bowels, from which recovery may only take place gradually as cooler weather arrives. In all cases relapses, brought on either by re-infection, by meteorological conditions, or by injudicious feeding, are extremely common and apt to prove fatal.

In children above the age of 2 the disease usually assumes a milder form—prostration is not so severe and the range of temperature lower. Vomiting, also, is a less prominent symptom than in infants. Complete recovery is more frequent, and relapses and the continuance of the disease in a chronic form are rare.

In the special type of the disease commonly spoken of as "cholera infantum" the invasion is always abrupt, with a rise of temperature, followed by profuse vomiting and purging. Prostration is marked from the outset. The stools are frequent and large, and though greenish and slimy at first quickly become watery, colourless and almost odourless. Thirst is intense, and the infant rapidly becomes shrunk and dehydrated. Death usually ensues in a few hours, and is commonly attended by hyperpyrexia.

Diagnosis.—The diagnosis has to be made from simple non-infective diarrhoea. At first the differentiation may be impossible, but continued high temperature, early prostration and failure of rapid improvement on stopping food point to an infective origin. Epidemic prevalence is also in favour of the more severe variety. The nervous symptoms may simulate those of meningitis, but in case of doubt a lumbar puncture will determine the diagnosis. Very acute cases, in which the colon is much involved, may

resemble intussusception, but in the latter the onset is more dramatically sudden, the vomiting, collapse and passage of blood greater, and fever less, whilst in epidemic diarrhoea abdominal rigidity and tumour are absent.

Prognosis.—It is impossible to give any estimate of the fatality of diarrhoea, as it depends greatly on the type of the disease, and on the age, general condition and surroundings of the child, besides varying greatly in different epidemics. The younger the infant, and the poorer its general nutrition, the worse is the outlook. The existence of rickets also greatly aggravates the danger. The frequency of the stools is of less importance in estimating the chance of recovery in any given case than the amount of prostration and the degree of inelasticity in the skin. Cases with prolonged high temperature and those of the choleraic type usually do badly. Persistence of vomiting also is a bad sign.

Treatment.—Unfortunately there is no specific treatment, and the principles to be aimed at are: (1) to stop the infection; (2) to eliminate and neutralise toxins; (3) to combat collapse; (4) to arrest the vomiting and purging.

1. In attempting to stop further infection, general hygienic measures are of great importance. Whenever it is possible, the child should be removed from a town, and isolated in a large, airy and well-ventilated room. Napkins should be removed and disinfected as soon as they are soiled, and the greatest cleanliness should be observed in regard to the feeding utensils and the nurse's hands.

If the case comes under observation early, an initial purge of castor-oil or, if there be much vomiting, of calomel should be given to clear away decomposed matter from the bowel. Milk, which is the vehicle of infection, should at once be stopped, and so long as the symptoms are severe, the diet should be limited to plain water, albumin water, barley water, weak tea, rice-water, 7½ per cent. glucose, or weak broths, all of which may be given freely.

2. In order to favour the elimination of toxins, the action of the skin and kidneys should be promoted as much as possible. To this end, if the skin be very inelastic, tepid packs are useful, and these may be continued, if necessary, for several hours on end. If the urine be scanty, a few drops of sweet spirits of nitre may be administered, and water should be given freely.

In the early stages of the disease no attempt should be made to arrest the diarrhoea entirely, as the retention of poisons would then be favoured. In addition to the initial purge, irrigation of the colon is a valuable aid in removing toxic material. Normal saline administered at a temperature of 100° F. through a long rectal tube or large-sized red rubber catheter is the best solution to employ.

The direct neutralisation of the toxins is, unfortunately, not at present practicable, as no efficient antitoxic serum for the disease has yet been found.

3. Collapse has to be obviated by saline infusion and the use of stimulants. Four ounces of normal saline may be injected under the skin of the flank every 6 hours.

Of stimulants, one of the best is alcohol. Ten to 15 drops of brandy may be given in a little water every 3 or 4 hours, or oftener; it should not

be added to the feeds. Camphor is also useful, and is best given dissolved in olive oil (1 in 15 or 1 in 30). Five minims of this solution may be injected under the skin as often as is thought necessary, or a few drops of spirits of camphor may be given by the mouth. If the collapse is extreme, recourse may be had to the mustard bath.

4. The arrest of the vomiting and especially of the diarrhœa is really a secondary object of treatment. For the vomiting, lavage of the stomach is the best treatment, particularly in the early stages, and a poultice may be applied to the epigastrium. Drugs are of little help, but small repeated doses of calomel (*e.g.* $\frac{1}{6}$ grain every hour for six doses) are sometimes useful. Chloro-tone in 1-grain doses may also be used cautiously. Iced champagne diluted with an equal quantity of soda water is sometimes of service.

As has already been pointed out, no active steps should be taken to arrest the diarrhœa at the onset. If it continues, however, and seems to be contributing to the exhaustion, one may try to reduce the frequency of the stools. In the early stages, small repeated doses of castor oil are useful for this purpose, and later, when the tongue is clean, bismuth, chalk, catechu and other astringents, as in the case of simple diarrhœa, may be used. A powder composed of 5 grains of bismuth carbonate, with $\frac{1}{16}$ th grain each of Dover's powder and calomel, is also a frequent prescription at this stage. Opium should not, however, be given at the outset, and it is best withheld so long as prostration is marked and the temperature high. When prescribed, it may be given in the form of the tincture in the proportion of 1 minim for every year of the child's age. It is specially indicated when the motions are frequent and attended by much colic and tenesmus. In cases of the choleraic type, with much vomiting and profuse purging, morphine may be given hypodermically with great advantage. The dose for a child of 1 year is $\frac{1}{60}$ th grain, with which $\frac{1}{100}$ th grain of atropine may be combined. This may be repeated in an hour if the symptoms have not abated.

"Intestinal antiseptics" are of little help, and may easily be injurious. The best are salicylate of bismuth, salol and resorcin. If the stools are very watery, nitrate of silver is the most powerful astringent.

After the acuter symptoms have passed off one must return very gradually to ordinary diet. Milk should be given at first malted or fully peptonised and freely diluted with lime water, or condensed or desiccated milk (*e.g.* Glaxo) or one of the patent foods (*e.g.* Allenburys) may be used in place of it. A feed may be given every 4 hours, and water between if the child is thirsty. Any return of the vomiting or diarrhœa must be the signal for again giving up milk in any form. During convalescence change of air and mild iron tonics are of service in restoring the child to complete health. Relapses, which are frequent, must be guarded against with the greatest care.

ROBERT HUTCHISON.

DIARRHŒA IN THE TROPICS

Ætiology.—Diarrhœa is a very common complaint in the tropics, and may only indicate some ordinary simple disturbance, such as bad food, indiscretions in diet, chills, etc. On the other hand, many of the more serious bowel maladies often start with a simple diarrhœa, and it is important

therefore to examine the stools to determine if any specific parasite be present or not.

The intestinal flagellates, such as *Giardia lamblia*, *Trichomonas hominis* and *Chilomastix mesnili*, have been incriminated by some as causes of diarrhœa, and it is difficult to deny the statement. Threadworms, *Enterobius vermiculatus*, and some of the flukes, *Heterophyes heterophyes* for example, also cause diarrhœa.

Diagnosis.—The stool must be examined for protozoal and other parasites before deciding upon the diagnosis.

Treatment.—If a simple ordinary diarrhœa, then a dose of castor oil with tincture of opium is all that is required in most instances, with, in more severe cases, rest in bed for a day or two and a milk diet.

HILL DIARRHŒA

Definition.—A peculiar form of diarrhœa occurring among the inhabitants of the hills in India and other parts of the world. Characterised by the passage of pale-coloured frothy stools in the mornings, with dyspeptic symptoms and much flatulence.

Ætiology.—The condition is not known to occur outside the highlands of India, Europe and South America. An elevation of 6000 feet is the most favourable to its development. Both sexes and all ages are liable. The exact cause is unknown. Crombie believed the condition to be primarily a dyspepsia, the diarrhœa being secondary.

Symptoms.—The diarrhœa comes on in the morning, a few days after the patient arrives at the hill station. The stools are copious, and of a very pale colour. For the rest of the day the patient feels quite well, only, however, to undergo a similar attack the next morning and so on. The flatulence which accompanies the diarrhœa is often troublesome and very uncomfortable.

Diagnosis.—This is easy, and can hardly be mistaken for anything else, unless it were the commencement of sprue in a person infected with that disease, travelling to the hills.

Prognosis.—This is quite good, but real sprue has been known to follow hill diarrhœa. A person subject to the latter should not for this reason risk too many visits to the hills.

Treatment.—Cases often become acclimatised and recover spontaneously. The patient should rest, preferably in bed for a day or two, and take nothing but milk. A drachm of liq. hydrarg. perchlor. may be given 15 minutes after food. If these means do not suffice the patient must return to the plains.

SPRUE

Synonyms.—Cochin-China Diarrhœa; Psilosis; Ceylon Sore Mouth, etc.

Definition.—A subacute inflammatory condition of the mucous membrane of the alimentary canal, associated with wasting, anæmia, peculiar white frothy stools and various lesions of the tongue and buccal mucosa.

Ætiology.—The disease is found in the tropics and subtropics. It is especially common in China, Cochin-China, India, Ceylon, Java, the Federated Malay States, and in Porto Rico in the West Indies. Europeans

living in the endemic areas are specially prone to infection: natives also suffer. Both sexes are affected equally. The definite cause is still unknown. *Monilias* have been described in the disease, but are probably only secondary contaminators. A hot damp climate appears to be essential, or at any rate to favour the production of the disease. Some deficiency in food has also been suggested, and a local house infection has been mentioned. This would indicate some infectious agent, or that the conditions necessary for acquiring the disease existed in that individual place. *Strongyloides intestinalis* was also once suspected, but there is no proof that such infections have anything to do with the disease. Sprue has been noted to follow, or to be superadded fairly frequently upon, amoebic dysentery.

Pathology.—The intestines are much thinned and the tissues generally wasted and anæmic. The changes in the mucous membrane of the bowel consist of shrinkage of the villi, round-celled infiltration, dilatation of the vessels of the submucosa, and the formation of slight fibrosis. As the changes progress, the villi and glands may entirely disappear, the atrophy becoming extreme. In addition, there may be small cystic dilatations of the follicles and even small abscesses in places. Finally, areas of the mucosa, chiefly in the lower end of the ileum and in the colon, become eroded, and definite ulceration may be seen. The changes described may be general throughout the bowel, but more often the condition is patchy and unequally distributed. The pancreas may show some fatty and granular changes with inflammatory infiltration of the connective tissue; the liver is atrophied. The tongue shows denudation of the epithelium with subacute inflammatory changes analogous to those of the bowel; yeasts may be seen invading the lesions.

It can readily be understood then, that with such a condition of the mucosa of the bowel, absorption must be seriously interfered with, and this perfectly explains the clinical conditions found. The pancreatic juice is defective in quantity and quality, the fat-splitting ferment especially, as large amounts of fat are passed in the motions, the total fats often reaching as high as 70 to 80 per cent. or over. Normally the fat in the stools is neutral fat 1, fatty acids 2, or 1-2. In sprue the relationship of the two is changed to neutral fat 1, fatty acids 5, or 1-5, or even higher. This helps to differentiate sprue from pancreatic disease (cancer of pancreas, etc.), where the neutral fat may be as high as 15, fatty acids 1, or 15-1. Bile is secreted in ordinary amounts, but the normal colouring matter, the bilirubin, is either not formed, or is changed in the intestine into leuco-urobilin, and this accounts for the peculiar white stools seen in the disease.

Symptoms.—The disease begins insidiously, the patient generally complaining of feeling tired easily, with listlessness and loss of energy. This is at first put down to climatic reasons, but later, a morning looseness of the bowels appears, necessitating an earlier rise from bed than usual. After breakfast there may be a further call and then for the rest of the day no more trouble. The weight begins to fall, and friends of the sufferer may note the colour of the face is gradually altering. The colour of the stools also changes, from the ordinary brown or yellow, to a white chalk-like appearance. The stools may be intimately mixed with bubbles of gas which give them a frothy appearance. Affection of the tongue, though sometimes completely absent, is usually a marked feature of the disease. The organ becomes very

painful and small spots or vesicles form on it and also on the buccal mucous membrane of the gums and cheeks. Ordinary diet can no longer be taken on account of the diarrhoea, and drinking and smoking often have to be stopped, on account of the pain they engender in the mouth. If the patient be not treated and stay in the endemic zone, he quickly gets worse, the emaciation becomes more marked and he finally passes into a chronic cachectic or marasmic condition, with a blood showing extreme anæmia, and dies.

When the malady follows on dysentery the onset is equally insidious, the dysenteric stools gradually changing their colour to a dirty white and becoming very bulky. The tongue and mouth then become affected and the condition becomes one of typical sprue, the stools in such cases still showing considerable amounts of mucus.

Physical examination reveals a great diminution of the liver area, with a peculiar loose flabby condition of the abdominal wall. The blood in the early stages shows moderate anæmia, later, in what may be described as the hamolytic type of the disease, the count may fall to below 1,000,000 per c.mm. Hæmic murmurs are then met with in the cardiac region. The leucocytes are normal or decreased, the hæmoglobin being as a rule equally reduced and giving a colour index of 1. There are some cases, however, where the blood closely resembles pernicious anæmia.

Course.—This will largely depend on the treatment the patient receives. This if suitable will cut short the disease in many instances, and may even cure it. In many cases, however, the disease is a very chronic one, lasting for years.

Diagnosis.—The cardinal signs of sprue are—(1) Loss of weight, generally marked. (2) Diarrhoea with white frothy stools, chiefly occurring in the mornings. (3) Tongue and mouth lesions. (4) Anæmia. (5) Shrinkage of the liver. With these signs present there should be no difficulty in diagnosis. Ordinary pancreatic disease, however, simulates it closely—interstitial pancreatitis, and cancer of the pancreas must also be borne in mind. Syphilis also may be mistaken, the tongue lesions resembling those of sprue in some instances. The bald tongue of syphilis often shows leucoplakia as well and the fissures are often transverse and deep. Both diseases may coexist. If this be suspected a Wassermann reaction should be done and, if positive, novarsenobillon should be given. Dysentery has been mistaken, but only by the uninitiated or superficial observer.

Prognosis.—This may be summed up in a word. It is good, if the patient be under 40 and will put himself under strict dietetic restrictions; bad, if he be 50 or older, though even in these cases much may be done by diet; many of these cases die, however, from the disease, the strictest treatment being of no avail.

Treatment.—The cause of the disease being unknown, little can be done to prevent its onset. If any signs appear, a removal from the endemic area to a temperate climate is at once indicated.

The treatment is one of diet, not of drugs. The patient must be put strictly to bed, and should be placed on milk alone, commencing with 3 pints a day given in feeds every two hours. It may be given raw, or diluted with lime water or barley water, or some of it may be peptonised. Rest is essential, and in most cases, after a week a distinct change for the better

appears, the diarrhoea disappearing and the tongue lesions subsiding. If the diarrhoea persists, *Pulvis bataviae*—a lime preparation—may be administered in 5i doses three times a day. When the bowels begin to function normally the milk is gradually augmented until as much as 7 pints a day are taken. The weight then begins to increase, and a solid stool, but still very white, is passed daily. After 6 weeks, a little arrowroot may be cautiously tried, and if this does not disagree, an egg can be beaten up in the milk, and the carbohydrate constituent of the diet gradually increased. Tapioca, sago, corn flour and semolina can all be given. About this time, *e.g.*, 3 months after commencing treatment, a change from the 2-hourly feeds may be made, a little more being given at the ordinary meal-times, with a reduction between. The patient may also be allowed up for an hour or two in the afternoon, and if all still go well (return of normal colour to stools, increase of weight, improvement of the anæmia), a gradual transition to a simple white meat diet—milk, fish, eggs, breast of chicken—is introduced. This must be continued for a year or more. If possible, sprue cases in England should go abroad to the Canary Islands for the winter, as this is a very bad time for them at home owing to the damp, cold and wet conditions which prevail. Little set-backs are from time to time experienced, and their cause, in many instances, is impossible to determine. The patient should not return to the tropics, or at any rate to any of the endemic foci. Recently, Dr. Harold Scott, having found that there is a deficiency of calcium in the blood in sprue, has suggested giving parathyroid gland and calcium as a routine treatment in the disease. The parathyroid is given in doses of $\frac{1}{10}$ of a grain twice daily, with calcium lactate grs. xv, 3 times a day. Some cases have done very well on this. A meat treatment has been suggested, but neither this, nor treatment with santonin, recommended by some, has given any success in the hands of the writer. The success claimed is due no doubt to the rest in bed. In the hæmolytic type of the disease with severe anæmia, whole blood transfusions have given excellent results in a series of cases belonging to the writer (Low and Cooke). A consideration of the morbid anatomy of the disease indicates how important are rest and simple diet.

No alcohol is allowed during the treatment, nor should it be taken afterwards either. Smoking is also contra-indicated.

G. CARMICHAEL LOW.

INTESTINAL CARBOHYDRATE DYSPEPSIA

Ætiology.—Intestinal carbohydrate dyspepsia is a common condition depending upon impairment in the digestive functions of the intestines independent of organic disease. Gastric and pancreatic digestion are generally normal, and no excess of proteins and fats is present in the stools. The digestion of starch, which is begun by the ptyalin of the saliva and amyllopsin of the pancreatic juice, should be completed by the diastatic ferment of the succus entericus. If this is deficient or if the softening of cellulose and its partial digestion by bacterial activity in the colon is incomplete, excess of starch, generally accompanied by excess of cellulose, appears in the fæces. Normally the small quantity of starch which reaches the colon

is rapidly digested. When excess is present, the normal enterococci multiply and produce large quantities of gas by their action on the starch. The excess of enterococci is not a result of infection, but is secondary to the carbohydrate indigestion, and disappears when the starch in the diet is so reduced in quantity that it can be dealt with by the saliva and pancreatic juice.

Symptoms.—Intestinal flatulence gives rise to borborygmi and to a sensation of fullness and pressure. As in the erect position gas from the transverse and descending colon collects in the splenic flexure, where the distension may cause palpitation and dyspnoea by pushing the diaphragm upwards, the discomfort is often mistaken by the patient for gastric flatulence and he consequently makes an effort to relieve himself by eructation; as there is no excess of gas in the stomach, his efforts result in aerophagy. Apart from this, the gas chiefly accumulates in the pelvic colon, so that discomfort is felt in the lower part of the abdomen. Distension of the intestines acts as a stimulant to their contractions, so that flatulence is often associated with colic, which is at once relieved by passing flatus. The discomfort caused by intestinal flatulence is a common cause of insomnia.

Microscopical examination of the stools shows the presence of excess of undigested starch, and generally also excess of vegetable debris, which can be recognised on simple inspection. On incubating the stool in a closed vessel connected with a gas-collecting bottle, a considerable quantity of odourless gas is evolved, and the stools, which are acid when passed, may become still more acid. A normal stool gives off no gas on incubation, and in putrefactive diarrhoea the alkaline stools evolve foul-smelling gas and become still more alkaline. On cultivation the stools are found to contain the normal number of *B. coli*, but a great excess of enterococci. No pathogenic organisms are found, and no toxic symptoms occur.

Diagnosis.—Patients tend to regard a sensation of fullness in the abdomen as invariably due to flatulence; if it is not felt in the region of the stomach, it is generally ascribed to excess of gas in the intestines. This explanation is often correct, the patient misinterpreting his sensations less frequently in the case of the colon than with the stomach. The only symptom, however, which proves conclusively that a sense of fullness in the abdomen is due to intestinal flatulence is its disappearance as a result of passing an excessive quantity of flatus. When a patient with symptoms pointing to the presence of excess of gas under the left dome of the diaphragm finds that the passage of flatus gives him relief, but eructation does not, it is probable that the cause is a collection of gas in the splenic flexure: by means of the X-rays it is easy to ascertain whether excess of gas is present in this situation, especially if the position of the stomach is defined by the consumption of an opaque meal.

Though intestinal flatulence is generally due to intestinal carbohydrate dyspepsia, other possibilities must be considered. Most of the gas in the stomach in patients with aerophagy is expelled by eructation, but if air continues to be swallowed when the stomach contains no food, some of it passes into the small intestine, in which it is partly absorbed, but the rest reaches the colon and is finally expelled from the rectum as almost odourless flatus.

Deficient absorption of gas probably occurs in catarrhal colitis. Ab-

sorption is greatly diminished from the intestines in cirrhosis of the liver and in heart failure. It ceases entirely when the venous circulation is completely arrested: this is the cause of the extremely rapid distension which occurs when part of the bowel is strangulated in intestinal obstruction.

In constipation a part of the colon may contract so firmly upon the fæces it contains that the gas which is behind it cannot pass; retention of gas then occurs in addition to retention of fæces.

Treatment.—Intestinal carbohydrate dyspepsia at once disappears if the quantity of starch in the diet is sufficiently reduced. In slight cases all that may be necessary is to take no potatoes. In others, rice and other starchy puddings must be prohibited and the quantity of bread reduced. If, as is often the case, the stools also contain obvious excess of vegetable débris, salads must be avoided, and it may be necessary to give all green vegetables in the form of purées. It is unnecessary to restrict the consumption of sugar, the digestion of which is unimpaired.

It is doubtful whether the use of diastatic ferments really aids in the digestion of starch, as they are likely to be more or less completely destroyed by the acid in the stomach. As purely symptomatic treatment the administration of half an ounce of powdered charcoal two or three times a day is very useful, as it absorbs any excess of gas which may be present in the colon. A tablespoonful taken before or after dinner may act as an hypnotic by absorbing the intestinal gas, which has hitherto led to disturbed nights and even severe insomnia.

ARTHUR F. HURST.

ENTEROGENOUS CYANOSIS

Alterations of the colour of the circulating blood, resulting in cyanosis, are in the majority of instances due to the deficient oxygenation of the hæmoglobin. Of recent years, however, research has established the existence in rare cases of a cyanosis due to the presence of two other compounds of hæmoglobin, sulphæmoglobin and methæmoglobin.

Synonyms.—Various names have been employed to designate this affection: Enterogenous Cyanosis; Microbic Cyanosis; and Sulphæmoglobinæmia and Methæmoglobinæmia.

Pathology.—The condition of sulphæmoglobinæmia is certainly associated with the intestinal abnormality; and where drugs of the aniline group, nitrites and potassium chlorate can be excluded the same is probably true of methæmoglobinæmia. Wallis' observations point to the presence of a nitrite-producing bacterium, the result of whose action is the production and entrance into the circulation of a strong reducing body, which attacks the hæmoglobin, sulphæmoglobin or methæmoglobin being subsequently formed.

Symptoms.—The two conditions present very much the same clinical phenomena. In both, the prominent feature is the existence over long periods of a cyanosis not due to any of the more usual causes, often varying in intensity, but occasionally continuous for years. Whether intermittent or continuous the general health suffers; weakness of the muscular system, fainting attacks, dizziness and severe headache. In the more prolonged cases the patients may be reduced to the last stages of exhaustion. The

sufferers from sulphæmoglobinæmia almost without exception are obstinately constipated; methæmoglobinæmia, on the contrary, is usually associated with diarrhœa.

The colour of the face, mucous membranes, ears, lips, and hands is leaden blue, or blue with a mauve tinge, and the association of this tint with extreme muscular weakness, and the absence or slight degree of dyspnoea is very striking. In the intermittent cases the rapid change from a normal tint to the cyanotic colour or the reverse is remarkable. Apart from its colour, the blood is often normal, both in the number of red cells and in the amount of the hæmoglobin; but in the more severe examples there is deficiency in both respects. Nausea, vomiting and attacks of abdominal pain are also recorded; in one case two abdominal operations were undertaken for the relief of the pain before the condition was recognised. The fainting fits are occasionally alarming, since the patient may remain in a collapsed semi-comatose state for several hours. In spite of the severity of the disease in these cases there is seldom a fatal issue, although so far complete recovery has not often been observed.

Diagnosis.—In the absence of other causes of cyanosis the condition may be suspected, and suspicion converted into certainty by examination of the blood with the spectroscope; in some cases this can be done by inspection of the webs of the fingers or the lobes of the ears. But although so different from the spectra of all the other hæmoglobin derivatives that it is easy to say one or other is present, the spectrum of sulphæmoglobin is so similar to that of methæmoglobin that it will require expert spectroscopy to distinguish them. The varying association of diarrhœa and constipation affords valuable indication.

Treatment.—Successful treatment has been directed to the intestinal affection; some cases of methæmoglobinæmia have been relieved by a prolonged milk diet; in one case a single meal of meat caused a return of the cyanosis. Sulphæmoglobinæmia has always been benefited by careful purgation, but in most instances this has not been sufficient in itself. Vaccines made from Wallis' nitrite-producing bacterium were efficacious in one case, but failed in others. In the attacks of collapse oxygen administered through an inhaler has proved of benefit; but, as would be expected, does not materially or permanently diminish the cyanosis.

HUGH THURSFIELD.

ORGANIC DISEASES OF THE INTESTINES

COLITIS

Inflammation of the colon may be general or localised to one segment. Thus inflammation of the cæcum (typhlitis), cæcum and ascending colon, pelvic colon (pelvic colitis), rectum (proctitis), or pelvic colon and rectum (pelvi-rectal colitis) may occur alone, but except in the case of the two last localisation is rarely absolute.

Although enteritis very frequently causes secondary colitis, the reverse is relatively rare, as infection and irritating material from the ileum must

pass along the colon before it is evacuated, whereas the ileo-cæcal sphincter prevents the spread of infection from the cæcum to the ileum.

The inflammation is generally limited to the mucous membrane, but it occasionally involves the deeper tissues and may spread to the peritoneum (pericolitis). The inflammation may be catarrhal or ulcerative, and chronic or acute.

ACUTE CATARRHAL COLITIS

Ætiology.—Acute catarrhal colitis occurs most frequently as a result of food poisoning. It may occur alone or associated with acute gastritis and enteritis. It may also be a symptom of specific fevers and various toxæmias, especially uræmia.

Symptoms.—The chief symptom is diarrhœa, the stools being frequent, fluid and offensive; they contain mucus, sometimes traces of blood, but no excess of food residue, unless the small intestine is simultaneously affected. Abdominal discomfort is present and paroxysms of colicky pain are frequent. In severe cases there may be well-marked general symptoms with a high temperature and a rapid pulse. As a rule the condition rapidly improves, but it may develop into chronic colitis.

Treatment.—Nothing but water should be taken by mouth during the first 24 hours; arrowroot, with the addition of sugar, but not milk, may then be given, but no further change in the diet is permissible until the diarrhœa has ceased, after which the return to normal diet should be gradual. The addition of a tablespoonful of powdered charcoal to each feed hastens recovery and reduces intestinal flatulence. No attempt should be made to stop the diarrhœa for the first 24 hours, but if it continues after that, opium may be given. The pain can be much relieved by the use of warm applications. The patient should be kept strictly confined to bed until the diarrhœa has ceased for 24 hours.

CHRONIC CATARRHAL COLITIS

Ætiology.—The most common cause of chronic catarrhal colitis is the habitual use of purgatives, which are frequently taken even in the absence of constipation. Infection of the bowels with pathogenic organisms, introduced in the food or water, or coming from some septic focus in the mouth, pharynx or appendix may cause a chronic, infective, catarrhal colitis, which may also be the sequel of an attack of acute colitis or the colitis of some specific infection, such as amœbic or bacillary dysentery.

Symptoms.—Diffuse discomfort and a sensation of fullness are commonly present in the lower part of the abdomen. Slight attacks of colic may occur, but in many cases there is no actual pain. The abdomen is often somewhat distended and tender. In many cases the catarrh is confined to one part of the colon, such as the cæcum or pelvic colon. The discomfort is generally worse after meals and is relieved if the bowels are well opened. In infective cases and those following an attack of acute colitis there is generally diarrhœa, mucus and occasionally traces of blood being found in the fluid stools, but there is no excess of food residue in uncomplicated cases.

The presence of mucus in the stools is often regarded as sufficient evidence

that colitis is present. But it is a function of the healthy mucous membrane to secrete mucus to protect itself against mechanical and chemical irritants. Consequently the unformed, clear mucus passed with hard fæces in constipation, and especially in dyschezia, does not indicate that colitis or proctitis is present, and the same is true of the mucus passed with fluid stools when irritating aperients have been taken. Only if mucus is passed with soft stools when no purgative has been given, can it be regarded as of any diagnostic importance. On the other hand, pus and red blood corpuscles both indicate the presence of some organic condition, though the possibility of hæmorrhoids as the source of the latter must, of course, be remembered.

Treatment.—The teeth should be put into good order and any other source of infection should be removed. The food must be thoroughly masticated and should be of an unirritating character. The use of purgatives should be avoided as much as possible, though liquid paraffin is often useful, as it makes the stools soft. In infective colitis capsules of *B. acidophilus* should be taken, and an autogenous vaccine may prove of value if definitely pathogenic organisms have been isolated from the stools. Belladonna should be given before meals with the addition, if diarrhœa persists, of codeine.

MUCO-MEMBRANOUS COLIC ; (MUCO-MEMBRANOUS COLITIS)

Definition.—In neurotic individuals constipation is sometimes associated with the constant or intermittent passage of membranes of coagulated mucus and with attacks of pain, the condition being known as muco-membranous colic. This name is preferable to “mucous colitis,” because mucus is passed in excess in all cases of colitis whether membranes are formed or not, and to muco-membranous colitis, except in the comparatively rare cases in which true inflammation of the colon is actually present.

Ætiology.—Muco-membranous colic occurs five times more frequently in women than in men. It generally begins between the ages of 20 and 45, but may occur at any age, and it is much more common among the educated classes than among ordinary hospital patients.

Pathology.—Two predisposing factors are invariably present—constipation, and the abnormally irritable nervous system which is characteristic of neurasthenia. Retention of fæces in an individual with an abnormally irritable nervous system may result in reflex over-activity of the motor and secretory fibres of the colon, leading respectively to painful spasm and to excessive secretion of mucus. If over-activity of the motor fibres occurs alone, colospasm results; this is analogous to pure spasmodic asthma. In other cases the spasm is associated with increased secretion of mucus. If the mucus is retained sufficiently long, coagulation takes place and a membrane forms. This is analogous with the formation of Curschmann's spirals in asthma. In most cases no actual catarrh is present unless the condition has been injudiciously treated with irritating purgatives or injections, when the membranes contain degenerated epithelial cells and leucocytes instead of being formed of almost pure mucus.

Symptoms.—In many cases the patients constantly suffer from chronic abdominal discomfort and pass membranes. In other cases definite attacks, which are sometimes brought on by depressing emotions, occur at intervals of weeks or months; the pain may be confined to the attacks, or there may

be abdominal discomfort in the intervals. It is, however, not uncommon for the presence of membranes in the stools to be the only symptom.

The pain is situated most frequently in the left flank and iliac fossa and just above the pubes; at the same time the descending and iliac colon are often tender and can be felt as a contracted cord, in which scybala can sometimes be distinguished. Less frequently there is pain and tenderness in the cæcum and ascending colon, which are felt to be more firmly contracted than usual; the condition may then closely simulate appendicitis, but no relief follows appendicectomy. The passage of faeces and membranes or of the latter alone, whether spontaneously or as the result of treatment, generally gives relief.

The constipation present in the intervals becomes much more severe during an attack. The stools consist of hard, small scybala, which may occasionally be moulded into thin or flat pieces owing to anal spasm.

The mucus is excreted as very thin membranous shreds, which may form tubular casts of the colon with a diameter of anything up to an inch and a half. They are often called skins by the patient and have been mistaken for tape-worms; they are sometimes rolled into a ball, which can only be disentangled by washing in water. The mucus may be transparent like ordinary mucus or opaque like fibrin; its colour is grey-white, but it is often stained by faeces and rarely by blood. The membranes may be passed alone or with scybala.

Muco-membranous colitis is occasionally secondary to the constipation which results from cancer of the intestine; it is therefore important to make a sigmoidoscopic examination in all cases in which no tumour has been felt by abdominal palpation or by digital examination of the rectum. In uncomplicated cases the mucous membrane is either normal or shows a very slight degree of catarrh. Symptoms of neurasthenia are generally present, and the patient always tends to become depressed and hypochondriacal.

Intestinal sand.—The passage of intestinal sand is almost always associated with muco-membranous colic. Small quantities of sand, which would otherwise escape detection, can often be discovered by running water on to the faeces placed in a muslin bag until the greater part is washed away. True intestinal sand must be distinguished from the false sand formed of wood-cells, which is sometimes passed by individuals who have eaten a large quantity of pears and more rarely of bananas. True intestinal sand is composed of pale yellow or reddish-brown granules, very irregular in shape and never crystalline. Their most characteristic constituents are the insoluble calcium soaps of palmitic and stearic acids; an approximately equal quantity of calcium phosphate is also present.

Prognosis.—Muco-membranous colic is a very chronic condition, and may persist as long as 30 years. If treatment is begun at an early stage, recovery generally follows, but when it has been present for many years the outlook is very unfavourable, and even if improvement occurs, the likelihood of a relapse is considerable.

Treatment.—A patient suffering from muco-membranous colic should be treated with the object of removing the two underlying factors—the abnormal condition of the nervous system and the constipation. It is very important to discourage him from making minute investigations of his stools; he should be told to be satisfied if he feels better without looking

to see how much mucus is passed. He may feel perfectly well in spite of the presence of mucus; but he will often only remain so for as long as he is unaware that he is passing it.

The constipation requires treatment by diet, massage, drugs and enemata. The best results are generally obtained with a generous mixed diet containing a plentiful supply of those articles which have already been described as useful in uncomplicated constipation on account of their chemically stimulating properties, but excluding raw vegetables in salads and pickles, fibrous vegetables such as celery, and the skins and pips of fruit. Mustard, pepper and spices of all kinds should be prohibited. Smoking should be restricted, and in severer cases should be entirely prohibited.

At the commencement of treatment any accumulation of faeces in the colon must be removed. This can best be done by enemata; in severe cases 6 ounces of paraffin should be injected in the evening and retained during the night. Once the colon is empty, the reaccumulation of faeces can often be prevented by the administration of liquid paraffin in order to soften the stools. If this does not result in the passage of a satisfactory stool each day, the further treatment depends upon whether the stasis is in the proximal part of the colon, in which case a mild aperient, such as infusion of senna pods, is required, or in the pelvic colon, when treatment by enemata without aperients is indicated.

As in the case of uncomplicated spastic constipation, belladonna is the most useful drug for combating the intestinal spasm; small doses of bromide may also be given to diminish the irritable condition of the nervous system. When the pain is severe it may be necessary to add codeine to the belladonna.

Local treatment of the mucous membrane of the colon by means of douches should only be used in cases in which other treatment has failed to give relief. As the patients are always self-centred, it is of the utmost importance to avoid encouraging them to concentrate upon their bowels and their excreta by irrigating the colon unless this is absolutely necessary. Intestinal lavage can be given at home; but it is generally more effective at one of the spas, such as Châtel-Guyon, Harrogate, Llandrindod Wells, Bath or Buxton, at which there are special facilities for carrying out the treatment.

Normal saline solution should be used if the treatment is given at home, and injections of soap and water, antiseptics and astringents should be avoided, as they tend to aggravate the condition by irritating the mucous membrane. At the various spas the natural waters are generally used for the purpose.

ULCERATIVE COLITIS

Ætiology.—Ulcerative colitis is a condition which occurs sporadically in England and other countries in which dysentery is not epidemic. Young adults are most frequently affected, and the disease is equally common in men and women. It is infective in origin, and from the very close similarity it bears to bacillary dysentery it seems probable that the unknown organism which causes it must be closely related to the *Bacillus dysenteriae*. In rare cases this organism has been isolated, and it has often been found in institutional epidemics of colitis and in the epidemic colitis of infants, conditions which are clinically and pathologically very similar.

Ulceration of the colon also occurs in rare cases of uræmia, probably as a

result of the excretion into the large intestines of toxins, which cannot be excreted by the diseased kidneys, and in mercurial poisoning. The rectum and pelvic colon may become ulcerated as a result of infection with gonococci, tubercle bacilli, streptococci or other organisms introduced per anum or invading them from neighbouring organs. None of these conditions should be included under the name of ulcerative colitis. The ulceration of the colon which occurs in typhoid and paratyphoid fevers is also of course distinct.

Pathology.—The primary change is an acute inflammation of the mucous membrane of the colon. Patches of localised necrosis then occur, and the gradual separation of the necrotic tissue leads to superficial ulceration. The floor of the ulcers is formed by the submucous or muscular coat, the ulcers tending to spread superficially rather than deeply.

Symptoms.—The onset is sometimes acute with severe diarrhoea and fever. More commonly it is subacute or insidious, the first symptom noticed being the passage of blood and mucus with or without diarrhoea. Even in cases which appear to begin acutely a history can often be obtained of slight intestinal irregularity, with the occasional passage of mucus or blood, for many months or even several years before the onset of severe symptoms.

Diarrhoea is always present; as many as 20 stools may be passed in the day. The stools are generally fluid and small in bulk. Blood, pus and mucus are passed in each, and often also alone without any faeces. In quiescent periods they may appear to be absent, but chemical and microscopical examinations show that this is not the case. Blood may be passed in large quantities alone; but it is generally mixed more or less intimately with the mucus and pus. It is bright red, and never produces black tarry stools, such as are seen with gastric and duodenal ulcer. It is mostly fluid; but small clots are often present. The mucus is unformed, and may be clear or opaque owing to the presence of pus; membranes are never passed. In most cases small collections of pus are easily recognised with the naked eye in addition to that mixed with the mucus and fluid faeces.

Abdominal discomfort is often, but not always, present. Actual pain is rare except immediately before defaecation, when colic may occur; this disappears as soon as the bowels are opened, especially if flatus is also passed. Tenesmus is unusual, and only occurs if the anal canal is involved. The abdomen is sometimes slightly distended, but in many cases it is retracted. Tenderness is often completely absent, even in severe cases, but pressure over the colon may cause discomfort. If the tenderness is considerable, the inflammation has generally spread to the peritoneum and local peritonitis is present; this is most commonly observed in the right iliac fossa and left iliac fossa. A moderate degree of muscular rigidity is often present in severe cases, especially when there is any local peritonitis.

Digital examination of the rectum is only painful in the rare cases in which the anal canal is inflamed. The thickened mucous membrane and the ulcers are readily felt with the finger when the rectum is involved.

A sigmoidoscopic examination should always be made. An anæsthetic is never required, and if the sigmoidoscope is carefully introduced under visual guidance without inflation, and only as far as it goes without difficulty, there is no danger. The mucous membrane is bright red, thick and sometimes granular. It bleeds very readily when touched, and small submucous

hæmorrhages are frequently seen. Its surface is covered with blood-stained, purulent mucus, some of which should be removed on a sterile swab for bacteriological examination. Superficial ulcers are invariably present; but in early cases they may be so small that they are difficult to recognise. Later they are large, and are sometimes so extensive that only small islets of mucous membrane are left, which may feel like small, flat polypi on rectal examination, the floor of the ulcers being mistaken for the surface of the mucous membrane. The ulcers are always superficial, with irregular edges; the thick mucous membrane is not undermined. The floor of the ulcers appears greyish-yellow when the blood and mucus are wiped from their surface.

In acute cases, and in acute exacerbations of more chronic cases, irregular fever is generally present. Apart from this, the patient has generally a good appetite. The constant diarrhœa leads to progressive emaciation and weakness; but in mild cases the patient may feel so well that he is unwilling to undergo treatment in bed. The loss of blood leads to secondary anæmia, which may be severe; the amount of hæmoglobin is often only 50 per cent. of normal, and may fall to 20 per cent.

Complications.—In the course of healing strictures, which may be multiple and of considerable length, may develop, especially in cases of long standing. A narrowing can sometimes be recognised with the sigmoidoscope, but the exact degree and localisation can only be discovered with the aid of an opaque enema. The symptoms generally do not alter with the development of the strictures, as the stools are so fluid that they pass without difficulty through the narrowed bowel. A case which resists treatment should therefore be examined for stricture, as, if one is found, a short-circuiting operation may be required.

In other cases healing is associated with the development of multiple minute polypi: this is probably the most common cause of polyposis of the colon. This condition may give rise to no symptoms, but the polypi are liable to become malignant. In my experience the application of deep X-rays invariably results in the complete disappearance of multiple polypi of this kind.

General peritonitis is a very rare complication, and is not due to perforation but to direct spread of infection through the wall of the colon. Localised abscesses are still more unusual.

Occasionally non-suppurative multiple arthritis develops, which is strictly analogous to the arthritis which may follow bacillary dysentery.

Diagnosis.—The association of blood in the stools with pus and mucus indicates the presence of ulcerative colitis, or a growth of the pelvic colon or rectum.

A growth can be excluded by rectal and abdominal palpation, and by the sigmoidoscope. Even if the growth is too high to be reached by the instrument its presence is rendered very probable when the accessible part of the colon appears normal, and blood, mucus and pus are seen coming from the inaccessible part.

If the patient has been in the East the possibility of dysentery should be considered, and even in the absence of such a history it is possible that a patient may have become infected by a dysentery-carrier living with him. Mucus obtained direct from the surface of an ulcer during the sigmoidoscopic

examination should therefore always be examined bacteriologically, and the agglutinating power of the patient's serum should be tested against various strains of *B. dysenteriae*. The sigmoidoscopic appearance of the mucous membrane in bacillary dysentery and ulcerative colitis is identical, but in the latter condition the serum very rarely agglutinates *B. dysenteriae*. Amœbic dysentery is, however, so distinct that a definite diagnosis can easily be made by the use of the sigmoidoscope alone. Small, round, red elevations are seen on the otherwise normal-looking mucous membrane, corresponding with the collection of 'broken-down' material in the submucous tissue caused by the invasion of *Entamœba histolytica*. In the centre of each elevation is a depressed yellowish ulcer where the submucous abscess has broken through the mucous membrane.

Prognosis.—Very acute ulcerative colitis may cause death in a few weeks. More commonly the condition becomes chronic, with periodic acute exacerbations, and thus approximates to the ordinary form of ulcerative colitis, in which the onset is insidious and the course very prolonged. Death generally results from cachexia, owing to the prolonged diarrhoea and constant loss of blood. With adequate treatment, however, recovery is the rule.

Treatment.—If a sigmoidoscopic examination is always made when a patient passes blood or mucus in his stools, or is suffering from diarrhoea, the cause of which is not obvious, ulcerative colitis can often be recognised at such an early stage that recovery will be rapid. More commonly, long-continued treatment is required, and no case should be regarded as cured until a further sigmoidoscopic examination has shown that all ulceration has disappeared and the mucous membrane is no longer inflamed.

The patient should be kept warm and recumbent in bed until no blood has been passed for a week, the bowels are not opened more than twice a day, and no ulceration and no inflammation can be seen with the sigmoidoscope. But the patient should continue under strict treatment till the mucous membrane appears to be perfectly normal, and he should be careful about his diet and keep his stools soft with liquid paraffin for several years, as the danger of recurrence remains for a prolonged period.

An abundant but light mixed diet should be given, as the stomach and small intestines are rarely involved. The food must be thoroughly masticated. Everything which could irritate the colon mechanically should be prohibited; vegetables are only allowed if they have been passed through a fine sieve, and no fruit except the juice or in the form of jellies.

The colon should be irrigated every day with tannic acid solution. An injection of a pint and a half of warm water should be given half an hour before, in order to clear away as much faeces, blood and mucus as possible; this should only be retained for about 5 minutes. The same quantity of the tannic acid solution (gr. i-ij to the ounce) is then run in very slowly at a pressure of not more than 12 inches of water through a tube introduced not more than 1½ inches beyond the anus, with the patient in the knee-elbow position. The fluid should be retained for gradually longer periods up to half an hour.

When the patient is very ill, as a result of long-continued loss of blood from the colon, transfusion of blood is of great value.

In my experience vaccine treatment has generally very little effect, doubtless because of the extreme difficulty of discovering the organism which

is really responsible for the colitis. If it can be identified with certainty, vaccination may be tried in addition to, but never as a substitute for other treatment. Sources of infection such as apical dental abscesses or pyorrhœa alveolaris should be thoroughly treated.

The intravenous injection of 50 to 100 c.c. of polyvalent anti-dysenteric serum daily for a week or 10 days may result in extremely rapid healing of the ulcers. The treatment is often so effective that the period of treatment is shortened from several months to a few weeks. In spite of the severe general reaction which occasionally takes place, serum should therefore be tried in every case. It may also be effective when given subcutaneously, but the treatment must be continued for a longer period.

The administration of half an ounce of finely powdered charcoal two or three times a day leads to the absorption of gas, and a great diminution of any colic which is present, as the latter is caused by intestinal flatulence. At the same time if the stools are offensive, they become odourless.

In chronic cases and in severe acute cases the question of operation requires consideration, if little or no improvement occurs after 3 or 4 weeks of strict medical treatment, but with the medical treatment described above I have seen very few cases in recent years in which surgery was required. The only operation likely to prove successful is appendicostomy, or, if the appendix has already been removed, a yalvular cœcostomy, which allows the introduction of fluid through a catheter, but not the escape of fluid fœces. The colon should be washed out continuously for 48 or 72 hours with saline solution introduced drop by drop through a catheter and allowed to escape from a bed-pan, upon which the patient lies. After this the colon is washed out with plain water once a day, and when all the fluid has escaped an antiseptic solution is introduced and allowed to escape when the patient wishes. The stoma should not be allowed to close until the sigmoidoscope has shown that the mucous membrane has completely healed. In my experience improvement after operation is not as a rule more rapid than under purely medical treatment, and the mortality is over 20 per cent., whereas in a consecutive series of 25 cases treated medically, many of extreme severity, recovery occurred in all but one.

TUBERCULOUS ENTERITIS AND COLITIS

Ætiology.—Miliary tubercles may be present in the intestines in general tuberculosis, but they have no clinical importance. Primary infection of the bowels from tuberculous milk is not infrequent in children, but is comparatively rare in adults. Secondary infection from swallowing tuberculous sputum is very common, ulceration being present in 50 per cent. of fatal cases of pulmonary tuberculosis, in some of which, however, it is probably due to pyogenic organisms and not to the tubercle bacillus. The lower end of the ileum, the appendix and the cæcum are the parts most frequently affected.

Symptoms.—In many cases no symptoms are present, although extensive ulceration may be found post mortem. Tuberculous enteritis should be suspected in children suffering from diarrhœa with fever, abdominal distension, enlarged glands, anæmia, wasting and weakness. It should also be

suspected when pulmonary tuberculosis is associated with diarrhoea, especially if abdominal pain and tenderness are present. But the diagnosis can only be made with certainty if tubercle bacilli are found in the stools, and with a considerable degree of probability if blood is passed. In the absence of abdominal pain the diarrhoea in advanced phthisis is generally due to the achlorhydria which is commonly present.

Perforation of a tuberculous ulcer is rare owing to the adhesions which form between the coils of intestine. Cicatrisation of an ulcer may lead to single or multiple strictures of the small intestines; as these are incomplete, and the contents of the bowel are fluid, obstruction is rarely produced. External adhesions and the formation of bands may, however, lead to acute intestinal obstruction. Tuberculous ulceration of the last few inches of the ileum may produce reflex dyspepsia similar to that caused by chronic appendicitis. In such cases the terminal ileum is tender and may be thickened; the stools generally contain occult blood, and there is often mild intermittent pyrexia. At a later stage small intestine peristalsis may become visible, and palpable stiffening of a coil of ileum, which disappears with a loud gurgle, sometimes occurs, although the bowels may remain regular until acute obstruction supervenes.

Hyperplastic tuberculosis of the cæcum is a very rare condition, in which the ileo-cæcal sphincter and a small part of the ileum may also be involved. Chronic intestinal obstruction and the presence of a hard, mobile, non-tender tumour give rise to suspicions of cancer, which can only be dispelled after exploration. It is rarely associated with tuberculous foci elsewhere and does not ulcerate, so that no pyrexia occurs and tubercle bacilli do not appear in the stools.

Treatment.—The treatment is that of tuberculosis in general, combined with the dietetic restrictions required for non-tuberculous colitis. Hyperplastic tuberculosis of the cæcum should be excised as soon as it is recognised.

CANCER OF THE COLON

Ætiology.—Primary columnar-celled carcinoma of the colon attacks men and women with equal frequency. It is most common between the ages of 40 and 65, although cases have been recorded in early childhood.

Pathology.—Only 3 per cent. of cases of intestinal cancer affect the small intestine. Of the remainder 60 per cent. are in the rectum and at the pely-rectal flexure, and 20 per cent. in the iliac and pelvic colon. Nearly half of the remainder are in the cæcum and ileo-cæcal region.

Extension to the peritoneum and secondary deposits in the lymphatic glands, liver and other organs occur later and rather less frequently with cancer of the intestine than with cancer in most other situations, obstruction occurring in more than 50 per cent. of cases before the glands are involved. The prospect of a radical cure by operation, if an early diagnosis is made, is therefore comparatively good, even when large portions of the intestine are involved. The rectum has a moderate supply of lymphatics, and gives operative results intermediate between the worse gastric and better intestinal cases.

Symptoms.—The possibility of cancer of the intestine should be con-

sidered whenever an individual above the age of 35, whose bowels have previously been regular, develops, without change of diet or habits, constipation or diarrhoea, or when a patient of the same age, who is habitually constipated, becomes more so without obvious reason. Constipation occurs earliest in the common annular form of intestinal cancer, which narrows the circumference of the bowel while the actual size of the growth is still very small. Less obstruction is caused by papillomatous carcinoma, which forms a friable and ulcerated mass, projecting into, but not obliterating, the intestinal lumen; constipation is at first intermittent and relieved by purgatives, which gradually become less effective and cause more pain. Enemata are generally of use for a longer period, but they also finally fail to act. Sometimes, however, there is persistent diarrhoea from the start, especially when the growth is situated in the pelvic colon. More frequently the initial constipation is interrupted by attacks of diarrhoea. In the majority of cases the constipation becomes steadily more severe until it ends in complete obstruction, which is sometimes hastened by the impaction of a hard mass of faeces in the narrowed lumen.

The stools do not generally differ in shape from those seen in ordinary constipation. Occasionally thin pieces, resembling the faeces formed in some cases of spastic constipation, are passed, especially when the growth is in the pelvic colon or in the rectum; they sometimes owe their shape to spasm of the anal sphincter, produced reflexly by the growth or by the irritating discharge from its surface; but I have also seen ribbon-shaped faeces appear through a stricture 6 inches from the anus during a sigmoidoscopic examination. The stools in cancer of the rectum and lower part of the pelvic colon generally contain obvious blood, pus and mucus; they may closely simulate those of simple ulcerative colitis, but fragments of more or less solid faeces can often be recognised, whereas in ulcerative colitis the faeces are always fluid. When the growth is proximal to the middle of the pelvic colon blood can rarely be recognised with the naked eye, but occult blood can always be found by the guaiac test; the spectroscope often shows that acid hæmatin as well as hæmatoporphyrin is present in contrast with the occult blood of gastric and duodenal origin, which only gives the former spectrum unless the quantity present is unusually great.

Vague discomfort in the lower part of the abdomen is often present, sometimes without any irregularity of the bowels, and slight attacks of colic occur when constipation becomes severe; but they rarely reach any great intensity until the obstruction is almost complete. In some cases, especially in cancer of the cæcum, hepatic flexure and splenic flexure, the pain always travels in a definite direction to a certain point, where the patient occasionally feels a rumbling sensation; this generally corresponds with the situation of the growth. When the pelvic colon is involved, the pain is always below the umbilicus and often most marked on the left side.

The over-activity of the colon above the obstruction leads to hypertrophy of its musculature. When the obstruction becomes complete, failure of the muscle ultimately occurs, and extreme paralytic distension results; ulceration and perforation, especially of the cæcum, may follow.

When the obstruction is sufficient to give rise to severe colic, strong, spasmodic contractions or "stiffening" of the intestine are often visible and palpable. They never occur in the colic associated with lead poisoning or

colitis, and only very rarely with obstruction due to simple impaction of fæces.

General symptoms of cancerous cachexia are generally absent in the early stage; they are most marked when the growth is extensive or much ulcerated, and when frequent small hæmorrhages have occurred. Progressive loss of weight and strength and increasing anæmia are the chief general symptoms; the appetite is often diminished, but the occasional association of a good appetite with progressive emaciation is, in the absence of pyrexia, very suggestive of a growth. The nutrition suffers most, and anæmia is most marked when the tumour is proximal to the splenic flexure, whereas obstructive symptoms are generally more severe when the distal part of the colon is involved.

In about 40 per cent. of cases a tumour is palpable when the patient is first seen, either on abdominal or rectal examination. In some of the remainder the growth is inaccessible to palpation, owing to its situation at the splenic flexure; in others the tumour is too small to be palpable. It is often impossible to reach a growth in the lower end of the pelvic colon or at the top of the rectum either by abdominal or rectal examination. In such cases the sigmoidoscope alone makes an early diagnosis possible. If acute obstruction is not an early occurrence, the growth develops into a large and easily palpable tumour, which invades the neighbouring peritoneum and viscera. The tumour often varies in size from time to time, as it is formed not only by the growth itself, but partly by impacted fæces or by thickened peritoneum and adherent coils of intestine, with perhaps a localised abscess. The disappearance of a tumour after treatment with purgatives or enemata does not therefore mean that cancer is absent, even if its disappearance is associated with improvement in the symptoms. For a mass of fæces can become impacted above a cancerous stricture and produce obstruction, which may be partially relieved when the fæces are removed. A diagnosis of cancer can only be excluded when the disappearance of the tumour is accompanied by complete and lasting cure of all the symptoms. The tumour produced by a growth is hard; it is rarely very tender, unless complicated by local peritonitis. When situated in the ascending, descending or pelvic colon it is generally fixed; in the cæcum and transverse colon it is frequently very movable.

The X-rays often afford considerable help in diagnosis. The shadow of the colon may be visible as far as the seat of obstruction unusually soon after the opaque meal; little or no barium may pass beyond this point for a considerable time. The passage of an opaque enema is often obstructed at a period in the disease when an opaque meal is not delayed. In some cases, especially when an enema is used, the actual narrowing of the intestine can be observed. When a tumour is present the combination of abdominal palpation and X-ray examination shows whether any delay in the passage of fæces occurs in the neighbourhood of the tumour, and whether the latter arises from some part of the alimentary canal. It is important to note, however, that the X-rays may completely fail to give any evidence of a growth until some months have elapsed since the onset of symptoms.

In exceptional cases symptoms are produced by complications before the intestinal functions become affected. Thus secondary deposits in the brain may cause cerebral symptoms sufficient to overshadow everything

else, and an abscess developing in connection with a stercoral ulcer above the obstruction, or general peritonitis resulting from perforation of a similar ulcer may constitute the earliest clinical manifestation.

Diagnosis.—The diagnosis depends upon the history combined with the results of abdominal and rectal palpation, examination of the stools for visible or occult blood, and with the sigmoidoscope and X-rays. A tumour in the right iliac fossa may be caused by an inflammatory mass developing round a small chronic appendicular abscess and by hypertrophic tuberculous disease of the intestine as well as by cancer. In the left iliac fossa confusion with an inflammatory mass in connection with acquired diverticula of the colon is not infrequent, but a barium enema almost invariably reveals the presence of the latter. The chronic obstruction caused by a local band of adhesions may simulate that caused by a growth, the difficulty being increased by the fact that the stools generally contain occult blood.

Treatment.—Cancer of any part of the large intestine proximal to the middle of the transverse colon is best treated by the removal of all the colon up to an inch beyond the growth, an ileo-colostomy being simultaneously performed. Beyond this point resection of the growth, with a sufficient margin on each side, with end-to-end anastomosis is more satisfactory. If obstruction is present, the operation should be performed in two stages, excision being only performed after the patient recovers from a preliminary colostomy or short-circuiting operation.

DIVERTICULA OF THE COLON

DIVERTICULOSIS : DIVERTICULITIS

Ætiology and Pathology.—Diverticula of the colon generally occur in individuals who have for many years taken aperients for constipation. Diverticula are uncommon above the middle of the descending colon, and increase in number and size as the lower end of the pelvic colon is approached, but they are very rare in the rectum owing to the thickness of its muscular coat.

Diverticula generally develop after the age of 40 and occur with equal frequency in men and women. Owing to the atrophy of the muscular coat of the colon, which occurs in old age, pressure from within produces diverticula more readily than in earlier life. The presence of fat diminishes the resistance of the intestinal wall to pressure from within, so that diverticula are especially likely to occur in the obese, and often form in the appendices epiploicæ.

A large number of diverticula are generally present; some are so small that they are barely visible to the naked eye, whilst others attain a diameter of half an inch. They very rarely become larger, as secondary pathological changes interrupt their growth. In the walls of the smaller diverticula all the coats of the bowel are represented. As they grow larger the muscular layer gradually disappears and the mucous membrane frequently becomes atrophied.

Symptoms.—Diverticulosis, the simple presence of diverticula of the colon, is a very common condition and gives rise to no symptoms. Their inflammation—diverticulitis—and still more inflammation of the surrounding
